This lesion is associated invariably with massive dilation of the pulmonary arteries and almost always with a ventricular septal defect. The murmur has been described as “sawing wood” in character and is not really continuous, but has more of a to-and-fro character. The massively dilated pulmonary artery

Figure 31.6. A: Lateral angiogram of a patient confirming a large ductal aneurysm (DAn) associated with a coarctation (Coarc). B: Lateral transverse aortic angiogram immediately after placement of covered stent for treatment of PDA aneurysm with associated coarctation.

evident on chest roentgenogram ordinarily allows for accurate differentiation.

Aortic Insufficiency Associated with a Ventricular Septal Defect

Prolapse of one aortic sinus complicates ventricular septal defects, particularly supracristal defects. The murmur is not strictly continuous, and the systolic murmur produced by the ventricular septal defect and the blowing regurgitant diastolic murmur produced by the incompetence are usually separated. However, accurate clinical differentiation may be difficult.

Peripheral Pulmonary Stenosis

Although commonly associated with a PDA, peripheral pulmonary stenosis may occur as an isolated defect and give rise to a soft, continuous murmur heard best in the infraclavicular areas and conducted to the axillae. Stenosis may occur in only one pulmonary artery, producing a unilateral murmur. This lesion may be difficult to distinguish clinically from a PDA.

Truncus Arteriosus

Truncus arteriosus may not be accompanied by cyanosis in early infancy, and with a low pulmonary vascular resistance and increased pulmonary blood flow, there may be a continuous murmur. Absence of the pulmonary artery segment on the posterior–anterior chest roentgenogram suggests this diagnosis; furthermore, the relatively common occurrence of right aortic arch with truncus arteriosus excludes the diagnosis of isolated PDA.

Aortopulmonary Window

This defect may be extremely difficult to differentiate from a PDA. The murmur commonly is heard best lower down the left sternal border and is often mistaken for the murmur of a high ventricular septal defect.

Pulmonary Atresia

When pulmonary atresia is accompanied by markedly enlarged bronchial arteries supplying pulmonary blood flow, a continuous murmur may be heard. However, cyanosis is present, and the peripheral pulses are not bounding as in PDA. The chest roentgenogram also shows absence of the pulmonary artery segment.

Complications

Endarteritis

Bacterial endarteritis has become extremely uncommon in developed countries, although it remains a serious complication of PDA. Because of the advent of surgical correction of many congenital heart defects, the prevalence of endocarditis, particularly in defects associated with left-to-right shunts, has declined dramatically (79). In one survey of major congenital heart defects, PDA had the lowest frequency, which was attributed to early surgical closure (80). In undeveloped countries PDA accounts for $\leq 15\%$ of all endocarditis cases and for 4.8 of 1,000 hospital admissions at a tertiary cardiac referral center (81). Organisms are typical with *Streptococcus viridans* and *Staphylococcus aureus* being the most common. Vegetations occur in $>80\%$ and are always seen on the pulmonary artery end of the duct.

Aneurysm/Calcification Formation

Marked dilation of a PDA or of the ampulla of the closed ductus arteriosus has been described (Fig. 31.7). The massive dilation that occurs may be diagnosed as a mediastinal mass.

Figure 31.7. CT scan of a young adult showing a large ductal aneurysm.

It also has been found as an incidental finding at autopsy. It occurs in $\leq 1.5\%$ of normal births (82). In adults calcification of the PDA is frequent and may increase the surgical risk (83).

Diagnostic Testing

Echocardiography

Two-dimensional echocardiography, combined with Doppler echocardiography and color-flow mapping is the primary imaging technique for evaluating the patient with a suspected PDA. A complete echocardiogram is particularly important prior to initiation of treatment to exclude any ductal-dependent congenital heart lesions.

In addition to directly demonstrating the presence of a PDA, echocardiography is used to evaluate the physiology. Features that are associated with an increased shunt through the PDA include the presence of LA dilation as demonstrated by an increased LA:Ao ratio as previously described. In addition, the presence of holodiastolic flow reversal in the abdominal aorta indicates a significant runoff through the PDA. This runoff is also demonstrated by increased diastolic flow in the branch pulmonary arteries. Finally, pulmonary artery pressure can be determined by the systolic and diastolic gradients through the PDA.

The parasternal short- and long-axis views and the suprasternal notch views are of particular use in evaluating the patient with a suspected PDA. The parasternal views demonstrate the size and anatomy of the PDA, the anatomy of the branch pulmonary arteries, and evaluate the LA and LV size (Fig. 31.3A–D). Doppler echocardiography can show the flow through the PDA as well as the increased flow in the branches. The suprasternal notch view shows a second view of the PDA, determines the patency of the aortic arch to exclude coarctation, and demonstrates the increased diastolic flow in the arch (Fig. 31.8A,B). Finally, the subcostal sagittal views demonstrate the abdominal aorta and show the diastolic runoff present due to ductal shunting.

Echocardiography can both predict and demonstrate the presence of low cardiac output in the premature infant who has undergone ductal ligation. PDA size prior to ligation directly correlates with the likelihood of postoperative low cardiac output (39).

Cardiac Catheterization with Angiography

Based on careful clinical evaluation—principally the characteristic continuous murmur, together with the ECG, chest roentgenogram, and two-dimensional echocardiogram Doppler study—diagnosis of PDA (and any associated defects) does not require catheterization. Color Doppler flow mapping is as sensitive as cardiac catheterization for detecting even a small PDA. In children with pulmonary hypertension, determining the exact location of the shunt can be more difficult. Contrast echocardiography can assist in the localization, but patients will require catheterization to determine the severity of pulmonary hypertension, reactivity to pulmonary vasodilators, and determine if closure is indicated.

Right heart catheterization alone usually suffices to confirm the diagnosis. However, if an additional lesion such as ventricular septal defect is suspected, retrograde catheterization may be required if the interatrial septum is intact and the LV cannot be entered prograde. The venous catheter usually can be passed from the main pulmonary artery through the PDA into the descending aorta. If the venous catheter cannot be passed through the PDA, retrograde aortic catheterization is indicated to define the anatomy with an aortic angiogram.

An increase of pulmonary arterial blood oxygen content of >0.5 mL/dL or a saturation increase of $>4\%$ to 5% from that in right ventricular blood indicates a significant left-to-right shunt at the pulmonary arterial level. Occasionally, an increase in oxygen saturation is noted in blood just below the pulmonary valve owing to pulmonary regurgitation. Because preferential streaming of oxygenated blood from the PDA into one or another of the branch pulmonary arteries is common, a sample from either one does not reflect mixed pulmonary arterial blood oxygen saturation (15). Measuring pulmonary blood flow accurately from the blood oxygen data is therefore difficult, making an accurate calculation of the true magnitude of left-to-right shunting impossible. In the presence of LV failure with pulmonary edema, pulmonary venous blood oxygen saturation may be reduced. If the foramen ovale is incompetent, a left-to-right atrial shunt may be detected by an increase in oxygen saturation in the right atrial blood. A large increase in oxygen saturation at the right atrial level may mask a smaller rise of saturation in the pulmonary artery, even though the increase represents a significant shunt at the pulmonary arterial level. With significant pulmonary hypertension and right-to-left shunting

through the PDA, oxygen saturation of blood in the descending aorta will be lower than that obtained in the ascending aorta. Bidirectional shunting may be present until pulmonary vascular disease is severe, when right-to-left shunting alone occurs.

A small left-to-right shunt may not be detected by blood oxygen saturation data alone. An increase in oxygen saturation in pulmonary arterial blood is not diagnostic of a PDA, but may be present in lesions such as aortopulmonary window or a high ventricular septal defect (supracristal), in which streaming may direct the highly saturated blood into the pulmonary artery.

With a small communication, pulmonary arterial blood pressures are normal, but systemic arterial pulse pressure may be slightly widened owing to a low diastolic pressure. With a moderate-sized defect, pulmonary arterial systolic, diastolic, and mean blood pressures may be slightly elevated. Systemic arterial diastolic blood pressure falls, whereas systemic arterial pulse pressure increases. Both left and right atrial mean pressures are moderately elevated in the presence of a moderate shunt. With a large shunt, pulmonary and systemic arterial pressures are equal (Fig. 31.9A,B), LA mean pressure may be increased substantially, and a prominent V wave is seen. LV end-diastolic pressure may be elevated, and with a large flow, a diastolic pressure gradient between the left atrium and LV is demonstrated. A small systolic pressure difference between the LV and aorta is also encountered occasionally when there is a large shunt. Because calculation of pulmonary blood flow in PDA is often inaccurate, the calculation of pulmonary vascular resistance is also inaccurate (15).

Angiography. Although angiography cannot accurately measure the magnitude of left-to-right shunting, it is the most effective test for defining the anatomy of the PDA. Contrast medium is injected into a catheter passed through the PDA into the aorta from the pulmonary artery or into the aorta retrogradely from the femoral artery. As shown in Figure 31.10A, the aortic end of the PDA usually is widely dilated, and the ductus narrows down at the pulmonary arterial end. This is the usual shape in most children, but occasionally other shapes are observed, including tubular (long ductus arteriosus of similar diameter throughout), complex (narrowing at both the pulmonary artery and aortic end), and short (window-like PDA) (84) (Fig. 31.10 A–E). In most instances the lateral projection, or occasionally the left anterior oblique projection, demonstrates the anatomy most clearly. The AP camera can be positioned in the right anterior

Figure 31.9. A: Simultaneous descending aortic (Ao) (red) and main pulmonary artery (MPA) (blue) pressure tracings in an infant with a large patent ductus arteriosus. Notice the resting tachycardia, elevated PA pressures, and low Ao diastolic pressure. B: Immediately after ductal closure with a vascular plug, repeat measurements show a marked reduction in heart rate, PA pressures, and an elevation in Ao diastolic pressure.

oblique caudal position to demonstrate the PDA. One should remember that in infants with severe heart failure associated with a ventricular septal defect or interatrial communication, a PDA may coexist; selective descending aortography is essential in these infants to exclude a PDA if not defined clearly by echocardiography.

Magnetic Resonance Imaging or Computed Tomography Scan

Although simpler techniques such as two-dimensional echocardiography Doppler evaluation accurately define the anatomy and flow patterns of the ductus arteriosus, nuclear magnetic resonance imaging (MRI) or computed tomography (CT) scan can clearly delineate the anatomy (85,86). These studies can be of use in adolescents or adults with poor echo windows where the diagnosis is suspected but not anatomically confirmed (Fig. 31.11), or in patients with associated aortic pathology such as a ductal aneurysm or coarctation. Velocity-encoded cine MRI imaging for estimation of left-to-right shunting may have additional clinical utility (87).

Treatment

Overview

All symptomatic PDAs with left-to-right shunting and those that are asymptomatic but causing LA or LV enlargement should be closed regardless of age. Management strategies are different for the preterm infant compared to the term infant, older child, and adult as described below. Prophylactic closure of hemodynamically insignificant PDAs for prevention of late complications such as endocarditis, aneurysm, and rupture remains controversial although is rarely considered, if at all before late toddler or school age. Patients with significant pulmonary vascular disease and right-to-left ductal shunting at rest should not have their PDA closed. Closure in these patients can be considered if aggressive treatment of their pulmonary vascular disease reverses their shunt.

Treatment of Preterm Infant with PDA

Aggressive, urgent treatment of a significant PDA in a preterm infant is required if signs of progressive respiratory distress or evidence of low cardiac output develop. This is particularly true if signs of necrotizing enterocolitis develop, including persistent abdominal distention, increasing residuals before feedings, blood in the stools or gastric aspirate, decreasing bowel sounds, and, particularly, intramural air. Immediate supportive medical management includes optimizing the hematocrit, limiting sodium and fluid intake, and the use of diuretics. If systemic output is quite poor, intravenous inotropic support with dopamine has been used. Maintenance of an adequate hematocrit and hemoglobin is an important consideration in a preterm infant with a PDA. A reduction in hemoglobin requires an increased cardiac output to maintain peripheral oxygenation, and with a left-to-right shunt and an already compromised myocardium, anemia may further impair cardiac function. In addition, because myocardial oxygen delivery depends on blood oxygen content, low hemoglobin exacerbates tissue ischemia, particularly in the abdomen and lower body where blood flow is reduced. Because arterial blood gas sampling is common, the hematocrit often decreases and care must be taken to maintain it >45%. Because peripheral tissue oxygen delivery is retarded by fetal hemoglobin, exchange transfusion replacing fetal hemoglobin with adult hemoglobin may help to facilitate peripheral oxygenation (22). Electrolyte, glucose, and nutritional requirements must be carefully maintained. Caloric intake is often a major problem, and intravenous hyperalimentation may be required. Because volume overload may precipitate LV failure, Na⁺ and fluid administration commonly are restricted to low maintenance amounts. Increased interstitial lung water related to pulmonary overcirculation results in tachypnea and increased work of breathing that should be acutely treated with diuretics, most commonly furosemide. All of the above are aimed at supportive treatment of a left-to-right shunt in anticipation of directly removing the shunt and its effects by closing the PDA. Options for closure include medical treatment, surgical division and ligation, and more recently catheter device closure.

Medical Closure. The use of oral or, preferably, intravenous (lyophilized) indomethacin to constrict the PDA has led to successful nonsurgical closure in a large proportion of treated infants (88–90); the effects of indomethacin apparently are best when it is administered before 10 days of age and in less mature infants. Originally, indomethacin was administered only to infants in whom standard medical management had failed and surgery was contemplated (88); however, it is now considered first line of therapy unless renal dysfunction or necrotizing enterocolitis is present. Dose schedules vary, but commonly a first dose of 0.2 mg/kg is given by nasogastric tube or intravenously. For intravenous indomethacin, subsequent doses depend on the age at initial treatment—if <48 hours, the subsequent two doses are 0.10 mg/kg; if 2 to 7 days, 0.20 mg/kg; and if >7 days, 0.25 mg/kg. A total of three doses usually are given 12 to 24 hours apart depending on urinary output; if urine flow decreases, fewer doses may be used or the time between doses may be extended. If clinical signs reappear after an initially successful course of therapy, a second course may be considered. Because signs of a shunt reappear in some infants, a more prolonged initial course of therapy has been suggested. Indomethacin should not be administered to infants with renal dysfunction (serum creatinine > 1.6 mg/dL or blood urea nitrogen > 20 mg/dL), overt bleeding, shock, necrotizing enterocolitis, or any suspicion thereof, or if there is ECG evidence of myocardial ischemia (91). The renal side effects of oliguria and hyponatremia do not always occur, and when they do they usually are transient; no obvious long-term adverse effects have been experienced (92). These renal side effects are more common, and often more severe, when significant fluid restriction precedes therapy. Administration to infants with PDA before they show obvious major hemodynamic complications has been used with good success, particularly in infants with birth weight <1,000 g (89). In this group of infants, the initiation of therapy is suggested immediately on diagnosis, which ordinarily is before 72 hours of age. True prophylactic therapy on the first day after birth appears to have no advantage, and because not all infants develop a PDA, a certain number would receive indomethacin unnecessarily.

Some studies have investigated combined treatment with indomethacin and inhibition of the nitric oxide pathway for very premature infants refractory to indomethacin alone (93). The combination of L-NMMA and indomethacin improved the closure rate, but the use adversely affected the creatinine and produced systemic hypertension, limiting its usefulness.

More recently, ibuprofen has also been evaluated as a possible alternative to indomethacin in preterm infants (94–99). In addition, meta-analysis of the available studies has shown a comparable rate of ductal closure after ibuprofen treatment (100–102). Some evidence exists that there may be less effect

of ibuprofen on renal function and urine output (94,95). In addition, ibuprofen has less effect on cerebral vasculature and cerebral blood flow but has not shown a decreased risk for intraventricular hemorrhage (96,98,99). However, in trials using ibuprofen for prophylaxis, there has been an increased incidence of pulmonary hypertension (103) such that this trial was ended prematurely. More recently, there is evidence that oral paracetamol may be an alternative to intravenous therapy (104).

In premature baboons, PDA ligation results in improved lung mechanics and ventilation at 14 days; however, there is no effect on histologic progression of chronic lung injury (105). Improved lung mechanics have been confirmed in premature infants at 26 to 29 weeks of gestation after ligation showing an increase in dynamic compliance, tidal volume, and minute ventilation (106). The benefit of treatment in premature infants with lung disease has been confirmed in a retrospective study showing a fourfold mortality risk for infants <28 weeks with persistent PDA after medical treatment as compared with those without PDA or those successfully closed (107). However, the timing of treatment remains controversial, because there is no demonstrated long-term benefit to early treatment (108).

Surgical Closure. If medical treatment is unsuccessful or not possible, surgical or catheter device closure can be performed. Surgical closure before 10 days of age reduces the duration of ventilatory support and hospital stay and lowers morbidity (109). Despite the small risk of recanalization, ligation rather than division of the ductus arteriosus has been recommended, although many surgeons still clip ligate to minimize the need for dissection and associated injury. Surgery now can be performed with minimal morbidity and mortality (110). Thoracoscopic surgery is used at some centers to minimize the effect on chest wall mechanics (111). A recent comparative study confirms both excellent safety, with 0% mortality, and success, with 100% complete closure, with both techniques although it suggests a potential advantage for the thoracoscopic approach with less morbidity and cost (112). However, some infants do develop acute low cardiac output after ductal ligation thought to be due to the acute increase in afterload with a concomitant decrease in LV preload, more pronounced with a larger PDA (39).

Catheter Device Closure. Technological advances have reduced the size of catheter PDA closure devices to allow delivery through 4 French catheters, outer diameter < 1.3 mm, making device closure a possibility for even small preterm infants (Fig. 31.12 A,B). Although not common practice, there is increasing use of these devices, with reports of successful implants in infants < 1.5 kg (113,114). The devices are delivered antegrade from the femoral vein. Ongoing concerns with

Figure 31.12. A: Lateral fluoroscopy image of delivery of a vascular plug into the tubular PDA of a 2.3 kg infant through a 4 French (1.3-mm-diameter) long sheath. B: Right anterior oblique aortic angiogram after release of the vascular plug showing complete closure of the PDA.

this technique include late femoral vein thrombosis and risk of device embolization with potential severe sequelae. Experience is too small at this time to quantify these risks accurately, so at present time, this has been used in patients at increased risk for either medical or surgical closure. As experience and improvements continue, this may become appropriate therapy for many preterm infants.

Prophylactic Closure. Despite the efficacy of treatment of the PDA in preterm infants, significant morbidity remains. Therefore it would seem that early closure before the development of clinical symptoms may reduce associated morbidity. Indeed, prophylactic administration of indomethacin in preterm infants prior to 28 weeks of gestation decreases the incidence of serious pulmonary hypertension, grade III/IV intraventricular hemorrhage, and need for surgical closure, but has not been shown to alter mortality (115). Prophylactic ibuprofen also decreases the need for symptomatic treatment but has not yet been shown to alter the incidence of intraventricular hemorrhage (116). In addition, one trial reported an incidence of significant pulmonary hypertension after prophylactic ibuprofen administration (103). Although the issue has not been put to rest, current practice is not to prophylactically close PDAs in preterm infants, even extremely low-birth-weight ones.

Treatment of Term Infants, Children, and Adults with PDA

In term infants or children, the complications resulting from isolated PDA, including failure to grow, recurrent respiratory infections, cardiac enlargement and failure, lobar emphysema or collapse, bacterial endarteritis, and the development of pulmonary hypertension are all indications for early correction. In adults, indications are more typically left heart enlargement, exercise intolerance, or bacterial endarteritis. Because treatment of an uncomplicated PDA is accompanied by minimal risk, closure should be recommended soon after the diagnosis is made. There is a small chance of spontaneous closure during the first 6 months of life so most pediatric cardiologists wait until about 9 months of age in asymptomatic infants. Treatment options

currently include catheter coil or device closure or surgery, with catheter closure having become the treatment of choice in most patients due to equal efficacy, fewer complications, and shorter recovery times (117). Indomethacin is ineffective in term infants and older children and therefore should not be used. If severe heart failure is present, medical management with intravenous diuretics, inotropes, and mechanical ventilation may be beneficial (118) prior to immediate catheter or surgical closure.

Catheter Coil/Device Closure. Catheter closure with occluding coils has become the treatment of choice for a small PDA (<2.5 mm in diameter). This 2- to 3-hour outpatient procedure is performed in the catheterization laboratory using conscious sedation, allowing discharge the same day with return to full activity the next day. A catheter is advanced from the femoral artery or vein across the PDA. An occluding coil is placed in the PDA with a single coil loop on the pulmonary artery side and the remaining three to four loops in the aortic ductal ampulla (Fig. 31.13A,B). Occasionally, immediate placement of a second or third coil is needed to achieve complete closure. This procedure is >97% successful with no mortality and minimal significant morbidity (119,120). Catheter technology has advanced so that coils currently used are made of platinum or a metal composite that is MRI compatible, resolving the previous issue of chest MRI artifact due to stainless steel PDA coils. For PDAs larger than a few mm but <12 mm in diameter, specialized devices, such as the Amplatzer duct occluder or the PFM Duct-Occlud coil (Fig. 31.14A–D) are available for catheter-based repair. The procedure is similar in duration, risk, and recovery time to the coil closure procedure. The devices are implanted antegrade from the femoral vein or retrograde from the femoral artery using long catheters through sheaths sized 4 to 8 French (1.3 to 2.5 mm outer diameter) (Fig. 31.15A–C). There is a >98% complete closure rate at 6 months with minimal complications and no reported mortality (121–123). PDAs larger than 12 mm have been closed using septal closure devices (AGA septal occluder, AGA VSD device, NMT CardioSEAL device) (Fig. 31.16A,B) or covered stents in select cases (124).

B: Antegrade delivery of an 8 to 6 Amplatzer ADO I device through a 6 French sheath. C: Lateral transverse arch angiogram showing the device closing the PDA completely.

Surgical Closure. Surgery remains the treatment of choice for PDAs too large for catheter closure. The traditional surgical approach to closure of the PDA involves division or transection of the PDA through a lateral thoracotomy. Suture ligation without division has the potential for recanalization, particularly following single-suture ligation. Surgery is extremely safe with minimal mortality and morbidity. Hospital stays can be as short as 3 days, with return to full activity within 3 weeks. A recent surgical advance is thoracoscopic surgical closure. In this technique, three small 1.5-in incisions are made in the lateral thorax through which a thoracoscope and several surgical tools are inserted. Several surgical clips are placed on the PDA under direct visualization through the scope. Obvious advantages of this technique include less operative lung manipulation, less chest wall pain, faster recovery, and a smaller scar. Some critics of this new technique have raised concerns regarding the potential for tearing and hemorrhage with clipping of large PDAs, particularly in adults in whom the PDA may be calcified. This technique is increasing in use; early results show similar efficacy, shorter hospital stay, and lower cost but in at least one study a higher rate of laryngeal nerve injury compared with standard thoracotomy (112,125,126).

Treatment of Children and Adults with PDA and Pulmonary Hypertension

The decision to recommend closure of a PDA in a child or young adult with significantly elevated pulmonary vascular resistance is not simple. Catheterization is recommended in these patients to evaluate the pulmonary vascular bed's response to test occlusion with a balloon catheter and pulmonary vasodilators, such as oxygen and nitric oxide. If there is a good response, whereby a significant decrease in pulmonary artery diastolic pressure and decrease in calculated pulmonary vascular resistance occurs, closure is advised. Device closure should be considered in this setting if the surgical risk is increased because of significant pulmonary hypertension (127). However, if the response to test occlusion with pulmonary vasodilators is equivocal, the decision is considerably more difficult. Aggressive treatment with pulmonary vasodilators including home oxygen, sildenafil, bosentan, and/or inhaled iloprost should be considered with repeat catheterization in 4 to 9 months with repeat evaluation and consideration for device closure (128). Some patients respond extremely well and show significant improvement after PDA closure,

Figure 31.16. A: Lateral proximal descending aortic angiogram in an elderly patient showing a large window-type patent ductus arteriosus with marked dilation of both the main pulmonary artery (MPA) and descending aorta (DAo). B: Lateral proximal descending aortic angiogram after closure with a 28 mm CardioSEAL device showing an immediate small residual shunt.

whereas others show a progressive increase in pulmonary vascular resistance after closure. Therefore, careful monitoring and use of pulmonary vasodilators after closure is needed. The only contraindication to closure of an isolated PDA is severe pulmonary hypertension with irreversible pulmonary vascular disease and baseline right-to-left ductal shunting despite maximal medical pulmonary vasodilation. If the PDA is closed in these patients, they are incapable of maintaining an adequate systemic output in response to stress, and rapid deterioration and death frequently occur.

AORTOPULMONARY WINDOW

Aortopulmonary window, or aortopulmonary septal defect, is a relatively rare cardiac malformation. Since first described by Elliotson (129) nearly two centuries ago, just over 300 cases have been reported (129–143). It accounts for 0.2% to 0.6% of all cases of congenital heart disease (139). Nearly half of all patients have associated cardiac lesions, including aortic origin of the right pulmonary artery (131,134,141,144), type A interruption of the aortic arch (132,134,139,142), tetralogy of Fallot (130,133,139), and anomalous origin of the right or left coronary artery from the pulmonary artery and right aortic arch (135,139,145). More rarely, it is associated with ventricular septal defect (131,143), pulmonary (143) or aortic atresia (142), D-transposition of the great arteries (146,147), and tricuspid atresia (136).

The aortopulmonary septum is formed by the two opposing truncal cushions, which appear at the 9-mm stage, then rapidly enlarge and fuse, dividing the truncus arteriosus into separate aortic and pulmonary channels (148). Cells that migrate from the neural crest influence this division. Removal of neural crest tissue results in various arterial abnormalities including truncus arteriosus, transposition of the great arteries, and aortic interruption. However, aortopulmonary window is not seen when neural crest tissue is removed (149). In addition, unlike truncus arteriosus, aortopulmonary window has not been reported in association with DiGeorge syndrome

(150). In contrast to other conotruncal abnormalities, there is no known association with 22Q11 deletion (147,151,152). Finally, whereas type B aortic interruption is associated with truncus arteriosus, type A is seen more frequently with aortopulmonary window (134,139). Thus, although these anomalies involve the same region of the heart, they appear to be unrelated embryologically, not variants of the same disease.

In most cases, there is a defect in the proximal portion of the aortopulmonary septum, midway between the semilunar valves and the pulmonary bifurcation. The defect is variable in size, but most defects result in a large, generally continuous left-to-right shunt when the pulmonary vascular resistance falls, similar to other interarterial communications such as PDA or truncus arteriosus. Without corrective surgery, irreversible obstructive changes in the pulmonary vascular bed develop early, followed by death in the second decade, although patients surviving into the fourth decade have been reported (133).

Pathology

Following the immediate perinatal period, once hemodynamic changes have occurred, the heart is large, owing primarily to an enlarged, volume-loaded left atrium and LV. The branch pulmonary arteries are usually enlarged because of the increased pulmonary flow. The ascending aorta is often small, particularly in cases with a very proximal defect or with associated aortic arch anomalies. The aortopulmonary defect is a discrete area, variable in size, usually positioned midway between the semilunar valves and the pulmonary bifurcation. It has a regular edge and is usually circular, although a form has been described with a border that is not continuous but describes slightly more than one turn of a spiral (139).

Although several classifications have been presented, the one proposed by Mori et al. (141) is most commonly used (Fig. 31.17). It describes three types of aortopulmonary connection. Type I is the most common type described earlier: a small defect midway between the semilunar valves and the pulmonary bifurcation. Type II is a more distal defect, the distal

Figure 31.17. Classification of aortopulmonary window. A: Type I, proximal defect, midway between the semilunar valves and pulmonary bifurcation. B: Type II, distal defect, with posterior border absent and aortic origin of right pulmonary artery. C: Type III, total defect, incorporating defects present in both types I and II. (From Mori K, Ando M, Takao A, et al. Distal type of aortopulmonary window. Report of 4 cases. *Br Heart J* 1978;40:681–689, with permission.)

border of which is formed by the pulmonary bifurcation. This type is more commonly associated with aortic origin of the right pulmonary artery (131,134,141). Type III, a large, confluent defect involving essentially the entire aortopulmonary septum, is the most rare.

Manifestations

Clinical Features

The clinical features of aortopulmonary window are not specific but are those of a large left-to-right shunt, and clinically this lesion often mimics either a ventricular septal defect or a PDA or both. Signs of congestive heart failure (tachypnea, diaphoresis, failure to thrive, and recurrent respiratory difficulty) usually begin in the first weeks of life (133,135,141). Cyanosis usually is not present, although large defects can produce desaturation owing to bidirectional shunting and mixing at the arterial level. When aortic arch anomalies are present, the presenting symptoms may be those of metabolic acidosis when the PDA closes, and the aortopulmonary window may be masked.

Physical examination shows tachypnea, abdominal breathing, and overexpansion of the lungs with intercostal retractions. There may be a prominent right ventricular impulse at the left sternal border. The pulses may be bounding, indicating arterial runoff into the lungs. On auscultation, the second heart sound generally is accentuated and narrowly split, suggesting pulmonary hypertension. In some patients a prominent ejection click is heard in the pulmonic area (133,141). There is either a loud systolic ejection murmur at the left upper sternal border or a machinery-type murmur similar to that found with a PDA (141). Often a middiastolic rumbling murmur is present at the apex, indicating increased flow across the mitral valve.

Patients with very small defects may be asymptomatic. In these patients, the second heart sound may be normal, with only a systolic ejection murmur and possibly a middiastolic murmur audible at the apex. The defect in these patients may be mistaken clinically for a small ventricular septal defect and may be diagnosed accurately only during routine echocardiography.

Electrocardiographic Features

There are no characteristic ECG findings in patients with aortopulmonary window. Evidence of right ventricular hypertrophy usually is present, although biventricular hypertrophy may be present when the defect is large or has been present for some time (135,141). Rarely, the ECG is normal or shows only a mild degree of right ventricular hypertrophy suggested by an rsR' pattern in the right precordial leads.

Radiologic Features

The chest roentgenogram is indicative of a large left-to-right shunt. A moderately enlarged heart with prominent pulmonary vascular markings is usually present. The main pulmonary artery segment is usually pronounced, as are the LA and LV borders. The aortic knuckle usually is not prominent. The lung fields frequently show hyperinflation, and pulmonary edema may be present.

Echocardiographic Features

Two-dimensional echocardiography can accurately diagnose aortopulmonary window and generally describe any associated anomalies (Fig. 31.18). In addition, the lesion is readily diagnosed *in utero* using fetal echocardiography (153). The left atrium and LV are dilated owing to the large left-to-right shunt. The right ventricle may be hypertrophied, although not always. The semilunar valves usually are normal in both position and motion. The pulmonary arteries are significantly enlarged. The aortopulmonary window can usually be seen directly, but dropout is often seen in the aortopulmonary septal area of normal patients. Balaji et al. (130) described a “T” artifact at the edges of the defect to help distinguish it from normal dropout. In addition, color Doppler flow mapping demonstrates flow through the defect.

Doppler echocardiography is helpful in the diagnosis of aortopulmonary window, with findings similar to that seen in a PDA. Abnormal, continuous forward flow in the pulmonary arteries indicates the presence of an aortopulmonary communication (130) (Fig. 31.3C). Significant retrograde descending aortic diastolic flow is found in both the proximal aortic arch and the abdominal aorta (Fig. 31.8B); this is also in contrast to a PDA where the proximal arch has diastolic prograde flow. Doppler echocardiography also demonstrates the presence of pulmonary hypertension when pulmonary or tricuspid insufficiency is present.

Cardiac Catheterization

With current echocardiographic techniques, cardiac catheterization usually is not required. The right ventricular and pulmonary arterial pressures usually are at systemic levels (135,141). The LA pressure may be elevated from the left-to-right shunt and increased pulmonary venous return, whereas the LV pressure is usually normal. Aortic pressure usually is normal, but in the presence of large defects may have a decreased diastolic and widened pulse pressure owing to runoff into the pulmonary vascular bed. The catheter often can be manipulated directly from the main pulmonary artery through the defect into the ascending aorta.

Either an ascending aorta or main pulmonary angiogram will demonstrate the defect. An ascending aorta angiogram shows filling of the pulmonary arteries, including the pulmonary valve sinuses, and main and branch pulmonary arteries (141). It also will demonstrate associated aortic arch anomalies. A main pulmonary arterial angiogram shows filling of the ascending aorta, and when present, also can demonstrate anomalous origin of a coronary artery from the pulmonary artery (135).

Differential Diagnosis

Because aortopulmonary window is an extremely rare defect, the clinical features are often ascribed to a large ventricular septal defect, a large PDA, or persistent truncus arteriosus. The bounding pulses, wide pulse pressure, and continuous murmur, if present, indicate the presence of an arterial communication (133). Distinguishing aortopulmonary window from

Figure 31.18. A: Parasternal short axis showing a small type A defect (arrow) immediately adjacent to the aortic and pulmonary valve. B: Parasternal short axis of larger type A defect, again with normal origin of the right pulmonary artery. C: Parasternal short axis showing a type B/C defect with separate origin of the right pulmonary artery adjacent to the windows. D: Suprasternal view demonstrating an associated type A aortic arch interruption. E: Parasternal short-axis echocardiogram showing anomalous origin of the right coronary artery from the pulmonary artery.

either a large PDA or from persistent truncus arteriosus often is extremely difficult by physical examination alone. A systolic ejection or continuous murmur is also present in patients with PDA; however, significant clinical symptoms in the first weeks of life are very unusual. Patients with persistent truncus arteriosus usually have more arterial desaturation than patients with aortopulmonary window and the same degree of congestive heart failure, as the common ventricular outlet results in complete mixing. They often also have a diastolic murmur indicative of regurgitation of the truncal valve. The murmur of a ventricular septal defect usually is heard toward the base of the sternum, and the pulses are not bounding.

Treatment

Closure of the defect is indicated in essentially all patients with aortopulmonary window. The classical treatment is surgical closure of the defect. Since the first reported correction by Gross (137), several types of surgical correction have been attempted. Simple ligation (135) and division with suture closure of the defect (133) both have met with poor results. Although exposure and patch closure of the defect from the pulmonary artery is possible (135,137), most authors recommend a transaortic approach using a median sternotomy and cardiopulmonary bypass (135,141,154). This approach provides optimal exposure of the defect and also allows access for correction of associated defects, particularly arch anomalies and anomalous origin of either the right pulmonary artery or right coronary artery. In patients with aortic origin of the right pulmonary artery, the patch closure can be tunneled to include the right pulmonary artery in the repair (134). Some revisions have used a pulmonary artery flap to close the defect (155–157). This technique avoids the use of prosthetic material. More recently, several patients have undergone closure using various catheter-delivered devices (158–161), although this approach is likely not applicable for larger defects or those with anomalous right pulmonary artery origin.

The prognosis of patients with aortopulmonary window is excellent if surgical correction is performed early in life, before irreversible pulmonary vascular changes occur (154). Although long-term follow-up is limited, late complications of the defect in patients adequately repaired are unlikely to be significant. Patients with associated anomalies will likely be limited more by the associated anomaly than by the repaired aortopulmonary window.

Congenital Anomalies of the Coronary Vessels and the Aortic Root

D. Scott Lim ■ G. Paul Matherne

Coronary and aortic root anomalies represent a small but interesting group of malformations that may occur alone or in association with structural heart disease (1–3). Recognizing and identifying these anomalies has become an important part of the evaluation of complex congenital heart disease. In the absence of structural heart disease, coronary anomalies are also important in certain clinical situations such as dilated cardiomyopathy (4), hypertrophic cardiomyopathy (5), and sudden cardiac events in older children (6). This chapter reviews coronary artery development and anatomy, coronary anomalies in the absence of structural heart disease, coronary anomalies in the presence of structural heart disease, and aortic root anomalies. Coronary arteriovenous malformations are covered in Chapter 37.

CORONARY VASCULAR ANOMALIES

Embryology

The cells of the developing myocardium initially receive nourishment directly from circulating blood in the ventricular cavity. As the myocardium thickens and develops, the presence of multiple trabeculations allows close proximity of the myocardial cells to the ventricular cavity. These trabeculations then develop into a sinusoidal system that continues to minimize diffusion distance between myocytes and the circulation. It was previously thought that these sinusoids were the forerunners of the coronary vascular system, but new data have provided evidence for an epicardial origin of the coronary vascular system (7).

The new model of coronary vascular development (7) begins with formation of a proepicardial protrusion by cells of the primordial liver. These cells establish the proepicardium and epicardial cells and then migrate over the surface of the heart. The epicardial cells invade the forming subepicardial matrix and form the coronary vascular plexus. The epicardial cells then undergo epithelial mesenchymal transformation by an as yet undefined mechanism that probably involves multiple growth factors. Nascent capillaries then are associated with subepicardial mesenchymal cells to form mature vessels. It has now been shown that small vessels on the surface of the heart fuse and grow inward to penetrate the aorta rather than coronary buds from the aortic sinuses fusing with the coronary vessels (8).

New experimental data on the development of the coronary system implicate multiple growth factors as well as adhesion molecules and chemotactic factors in this complicated coordinated migration and transformation of cells to form coronary vessels. The presence of congenital anomalies of coronary arteries suggests abnormalities in these signaling pathways or alterations in local factors that direct coronary vessel development.

Anatomy

Coronary Arteries

Normal coronary artery anatomy is briefly reviewed, but for a complete discussion on this subject the reader is referred to Dr. Frank Netter's diagrams in the *CIBA Collection of Medical Illustrations* (9). The entire blood flow to the myocardium is derived from two main coronary arteries arising from the right and left aortic sinuses of Valsalva (Fig. 32.1). The left main coronary artery is about 13 mm long in adults (range 2 to 40 mm) and gives rise to the circumflex branch, which courses posteriorly in the atrioventricular groove; the left main coronary then continues as a left anterior descending branch. The right coronary artery gives rise to a small conal branch and then courses posteriorly in the opposite direction along the atrioventricular groove. There is no separate septal branch, the septum being supplied by perforating branches that enter the septum from the anterior and posterior descending coronary arteries. In 69% of the population, the right coronary artery is dominant (10), giving rise to the posterior descending coronary artery, which extends to the apex and supplies the posterior part of the ventricular septum, the inferior wall of the left ventricle, and the atrioventricular node (11). In 11%, the left coronary artery is dominant, thereby giving rise to the posterior descending coronary artery, and in 20% there is codominance (10). The left coronary artery supplies the free wall of the left ventricle. Interestingly, many patients with bicuspid aortic valves or aortic stenosis (20% to 57%) have left-dominant systems and a short left main coronary artery (10,12,13).

Within the myocardium, small arteries branch repeatedly until they reach the endocardium. Normally, there are connections between coronary arterial branches that are 25 to 200 mm in diameter and are known as collaterals. They may be superficial or subendocardial, and they are capable of enlarging if pressure gradients develop between branches. These collateral arteries become significant in cases of primary arterial occlusion, in which cases they may allow reperfusion of affected myocardium.

Cardiac Veins

The coronary sinus arises from the proximal portion of the left sinus horn and the common cardinal vein. The great cardiac vein begins at the apex and runs up the anterior interventricular groove to enter the coronary sinus just below the left lower pulmonary vein. The coronary sinus then courses around the left edge of the heart in the posterior atrioventricular groove until it enters the right atrium near the atrioventricular node. The middle cardiac vein runs up in the posterior atrioventricular groove to enter the coronary sinus. The posterior ventricular vein drains the free wall of the left ventricle up to the coronary sinus. The small cardiac vein runs with the right

Figure 32.1. Normal anatomy of the coronary arteries. coronary artery in the right posterior part of the atrioventricular groove; it drains into the coronary sinus or directly into the right atrium, as do the small veins draining the right ventricular free wall (14,15).

ANOMALIES OF CORONARY ARTERIES IN THE ABSENCE OF STRUCTURAL HEART DISEASE

Normal Variations

The right and left coronary arteries arise from the right and left aortic sinuses of Valsalva (Fig. 32.1). Usually they come from the middle of the sinuses, but they may arise from the sinotubular junction or even above it. The position of the ostium does not appear to affect the flow through it. The ostia may be round, oval, or elliptical. The arteries are usually perpendicular to the aortic wall; that is, they are radially arranged relative to the center of the aorta.

Separate origin of the conus branch of the right coronary artery commonly occurs (11). The corresponding anomaly on the left side—separate origins of the left anterior descending and left circumflex coronary arteries—occurs in about 1% of the population and is more frequent with bicuspid aortic valves (11). Neither of these anomalies appears to have any clinical consequence.

Abnormal Origin of Right or Left Coronary Artery from Inappropriate Sinus

Anomalous Origin of Left Coronary Arterial Branches from Right Sinus of Valsalva

The most common anomaly, accounting for about one-third of all major coronary arterial anomalies, is origin of the left circumflex coronary artery from the right main coronary artery (Fig. 32.2A) (2,3,16,17). The left circumflex coronary artery passes behind the aorta to reach its normal territory of supply. This anomaly has no general clinical significance, but the artery may be compressed if both mitral and aortic

prosthetic fixation rings are implanted. These anomalous arteries may have an unusually high incidence of coronary atheroma (2).

Much less common, accounting for 1% to 3% of major coronary arterial anomalies (2,16), but of greater clinical significance is origin of the left main coronary artery from the right sinus of Valsalva (1,16,18). There are four pathways that the left main coronary artery can take after leaving the sinus: posterior to the aorta (Fig. 32.2B), anterior to the right ventricular outflow tract (RVOT) (Fig. 32.2C), within the ventricular septum beneath the right ventricular infundibulum (Fig. 32.2D, the most common variant), and between the aorta and the RVOT (Fig. 32.2E). With rare exceptions, the first three courses have not been associated with sudden death or premature myocardial ischemia. The course that passes between the two great arteries, however, has often been associated with sudden death in people during or just after vigorous exercise. Several of these patients had had episodes of syncope or chest pain during previous exercise. In most of these patients, the ostium of the left main coronary artery was slit-like, with an intramural course within the aortic root and adherent to it for about 1.5 cm (18).

In some patients, the left anterior descending coronary artery originates in the right sinus of Valsalva or from the right main coronary artery (Fig. 32.2F). This anomaly is rare in the absence of congenital heart disease (2,18) but is common in tetralogy of Fallot. The artery usually passes in front of the RVOT or through the interventricular septum but has rarely been seen to pass between the aorta and RVOT. Should there be atheroma near the ostium of the common arterial trunk, most of the heart will become ischemic, so that the lesion is the equivalent of a left main coronary stenosis.

Anomalous Origin of Right Coronary Arterial Branches from the Left Sinus of Valsalva

Origin of the right main coronary artery from the left sinus of Valsalva, first described by White and Edwards (19) in 1948, is relatively common, making up about 30% of all major coronary arterial anomalies (2,18), and has a significantly higher incidence in Asians and Hispanics (20). The right coronary artery then courses between the aorta and the RVOT to reach the right side of the atrioventricular groove, after which it is distributed normally (Figs. 32.3 and 32.4). This anomaly was once thought to be benign, but there are now many reports of myocardial ischemia, infarction, or sudden death (21–23). In many of the autopsies, the origin of the right main coronary artery was angulated and the ostium was described as slit-like.

Single Coronary Artery

In 5% to 20% of major coronary arterial anomalies, a single coronary artery arises from the aorta and then branches (17,24). Sometimes an atretic cord connects part of the artery to a sinus of Valsalva that has no ostium. About 40% of these anomalies are associated with other cardiac malformations, including transposition of the great vessels, tetralogy of Fallot, truncus arteriosus, coronary-cameral fistulas, and bicuspid aortic valves. The single artery can arise from either the right (Fig. 32.5A–C) or the left sinus of Valsalva (Fig. 32.5D–F) with many variations (24). The single coronary artery on either side can follow its usual course and then continue on to supply the other side of the heart, or separate branches can arise from a main coronary artery and course posteriorly or anteriorly to supply the other side of the heart. Branches also can pass between the great vessels.

For the single coronary arteries arising from the right side, the right coronary can follow the course of the normal right

Figure 32.2. Anomalous origin of the left main coronary artery from the right sinus of Valsalva. A: Left circumflex coronary artery arising from the right coronary artery. B: Left main coronary artery arising from the right sinus of Valsalva (posterior course). C: Left main coronary artery arising from the right sinus of Valsalva (anterior course). D: Left main coronary artery arising from the right sinus of Valsalva (interventricular septal course). E: Left main coronary artery arising from the right sinus of Valsalva, and with a course between the two great arteries. Note the oblique origin of left main coronary artery (LMCA). F: Separate origin of the left anterior descending coronary artery (LMCA). A, aorta; LAD, left anterior descending coronary artery; LCX, left circumflex coronary artery; LMCA, left main coronary artery; P, pulmonary outflow; RCA, right coronary artery.

coronary artery and continue as the left circumflex artery, which then gives off the left anterior descending coronary artery (Fig. 32.5A). Alternatively, after the right coronary artery arises, a separate branch to the left side can arise that passes posterior to the aorta and gives rise to a circumflex vessel and a left anterior descending coronary artery (Fig. 32.5B), or the separate branch can follow a course anterior to the right ventricular infundibulum, giving rise to the anterior descending coronary artery before continuing on as the circumflex (Fig. 32.5C).

A single left coronary artery can display branching patterns similar to those on the right. A single left coronary artery can branch into the left anterior descending and left circumflex coronary arteries with the circumflex continuing across the crux to form the right coronary artery (Fig. 32.5D). A separate right coronary vessel also can arise from the single left coronary artery

Figure 32.3. Anomalous origin of the right coronary artery from the left sinus of Valsalva, with oblique origin and course between the great arteries. A, aorta; CB, conal branch of the right coronary artery; LAD, left anterior descending coronary artery; LCX, left circumflex coronary artery; LMCA, left main coronary artery; P, pulmonary outflow; RCA, right coronary artery.

and pass posterior to the aorta (Fig. 32.5E) to reach the opposite side of the heart or the vessel can pass anterior to the right ventricular infundibulum (Fig. 32.5F). Most single coronary arteries produce no symptoms in the absence of severe atheroma (which is clearly more serious when there is only one main artery supplying the whole heart), but a few premature deaths have been reported with this anomaly (24). It is usually those variants in which a major branch passes between the aorta and the right ventricular infundibulum that are at greatest risk for sudden death (24), but other patterns can cause myocardial ischemia.

Left or Right Coronary Arterial Branches Arising from the Posterior Sinus of Valsalva

These are very rare (18) and have not been associated with premature or sudden death.

Pathology and Clinical Features of Abnormal Origin of Right or Left Coronary Artery from Inappropriate Sinus

Pathology

In about 20% of autopsies there are subendocardial scars, and occasionally a major myocardial territory infarction is reported. However, the suddenness of death in most of these patients prevents large scar from occurring. Occasionally, severe atherosclerosis has been seen in a segment of the abnormal vessels, even in children (25). In some of the anomalies, the initial few millimeters of artery may run within the aortic wall. Finally, the anomalous artery may arise tangentially from the aorta, and its ostium may be slit-like and partly covered by a valve-like flap.

Mechanisms of Death

Death is almost certainly due to myocardial ischemia, but the exact mechanism is unknown. The left ventricular myocardium has a huge demand for oxygen during strenuous exercise. Systolic pressure increases during strenuous exercise, and there is activation of the sympathetic nervous system. The root of the aorta therefore distends in systole. If part of the anomalous artery runs within the wall, it may be compressed, and if the artery runs adjacent to the wall, it may be stretched, compressed, or both. Presumably, the severe myocardial ischemia

Figure 32.4. Three-dimensional reconstruction from computed tomographic imaging of the coronary arteries demonstrating anomalous origin of the right coronary artery from the left sinus of Valsalva, with oblique origin and course between the great arteries. Note the oblique origin of the right coronary artery, which then runs between the two great arteries. A, aorta; LCA, left coronary artery; RCA, right coronary artery; RVOT, right ventricular outflow tract.

that occurs from any of these mechanisms produces either ventricular fibrillation or electromechanical dissociation. In those with previous syncope, the severe ischemia might have produced transient ventricular tachycardia or fibrillation or else suddenly impaired ventricular function might have decreased cardiac output catastrophically. Why some patients with apparently identical anomalies survive without ischemia until their 70s and 80s is unknown.

Clinical Features

Most of these anomalous arteries do not cause myocardial ischemia, particularly if the anomalous branch does not pass between the aorta and the right ventricular infundibulum. Even those that do run between these structures do not always lead to sudden or premature death. However, this is the group that accounts for symptoms and sudden death in children, adolescents, and young adults. Although the first sign of the anomaly is sometimes sudden death or a fatal myocardial infarction, in many of these patients, there may be a history of syncope or prolonged chest pain before the fatal event. These symptoms almost invariably come on during or just after strenuous exercise, and many of the victims have been athletes.

Diagnosis

Any episode of syncope or of severe chest pain during or after exercise calls for intensive investigation. The standard clinical examination usually shows no abnormalities. A resting electrocardiogram should be performed to evaluate ventricular hypertrophy, evidence of prior infarction, and persistent arrhythmia. An echocardiogram should be performed to exclude persisting ventricular dysfunction, hypertrophic cardiomyopathy, and proximal coronary anatomy. Careful

attention should be directed to the origins of the coronary arteries because most of the anomalies affect the origins of the major arteries or their major branches and therefore may be detectable by echocardiography. Following the course of the coronary vessels is also important because the lesions with the highest risk of sudden death are associated with a major branch passing between the great vessels. Proving that a coronary artery passes between the great vessels can be difficult by angiography and may be easier by echocardiography. Because most patients are older children or adults, the resolution of the transthoracic echocardiogram may be inadequate to show the anomalies, and transesophageal echocardiography (26), magnetic resonance imaging (27), or computed tomographic scans (28) (Fig. 32.4) may be more sensitive.

Evaluating blood pressure and the electrocardiogram or injecting thallium at near-maximal exercise can be useful. However, a normal near-maximal stress test result has been reported in patients who subsequently died suddenly and had an anomalous left main coronary artery (29). Because of this, exertional syncope or severe exertional chest pain in a child or young adult warrants further investigation if the echocardiogram is inconclusive.

Anomalous Left Coronary Artery from the Pulmonary Artery

In this anomaly, the left coronary artery arises from the pulmonary artery, usually from the left posterior facing sinus (Fig. 32.6). This anomaly was first described by pathologists in 1866 (30), and by 1962 Fontana and Edwards (31) had collected descriptions of 58 necropsies with this anomaly. Most of these patients died at <13 months of age. The first report relating clinical and autopsy findings in a 3-month-old boy was by Bland et al. (32). The anomaly has thus been called the Bland-White-Garland syndrome.

Pathophysiology

In fetal life, this anomaly probably has no harmful effect: Pressures and oxygen saturations are similar in the aorta and pulmonary artery. Myocardial perfusion is presumably normal, and there is no stimulus to collateral formation (Fig. 32.6A). After birth, however, the pulmonary artery contains desaturated blood at pressures that rapidly fall below systemic pressures. Therefore, the left ventricle, with its huge demand for oxygen, is perfused with desaturated blood at low pressures. Collateral flow is initially low. The left ventricular myocardial vessels dilate to reduce their resistance and increase flow, but soon coronary vascular reserve becomes exhausted and myocardial ischemia ensues. At first, ischemia is transient and occurs only with exertion such as during feeding or crying, but further increases in myocardial oxygen demand lead to infarction of the anterolateral left ventricular free wall (Fig. 32.6B), with resultant compromise of left ventricular function. This causes congestive heart failure, which is often made worse by mitral regurgitation secondary to a dilated mitral valve annulus or infarction and dysfunction of the anterolateral papillary muscle. Collateral vessels between the normal right and abnormal left coronary artery enlarge, and with the increased flow, so does the right coronary artery itself (Fig. 32.6C). However, because the left coronary artery is connected to the low-pressure pulmonary artery, the collateral flow tends to pass into the pulmonary artery rather than into the high-resistance myocardial blood vessels. There is a pulmonary-coronary steal with a left-to-right shunt. The shunt is usually relatively small in terms of cardiac output but relatively large in terms of coronary flow. In about 15% of these patients, myocardial blood flow can sustain myocardial function at rest or even during exercise. These are the patients who reach adult life (33).

Figure 32.5. Single coronary artery variants. A to C: Single coronary artery originating from right sinus of Valsalva. A: Right coronary continuation to the left circumflex coronary artery (LCX) and left anterior descending coronary artery (LAD). B: Posterior course of separate LCX giving off the LAD. C: Anterior course of a separate LAD branch feeding back to the LCX. D to F: Single coronary artery originating from the left sinus of Valsalva. D: Left coronary artery giving rise to the LAD and the LCX, which then continues as the right coronary artery. E: Posterior course of separate right coronary branch off the left main coronary artery. F: Anterior course of separate right coronary artery coming off of the LAD. Variants passing between great vessels are not illustrated. A, aorta; P, pulmonary artery; RCA, right coronary artery.

Pathology

This anomaly is usually isolated but has been associated with patent ductus arteriosus (17,33), ventricular septal defect, tetralogy of Fallot, or coarctation of the aorta (33). If there is pulmonary hypertension, as with a large ventricular septal defect, left ventricular perfusion may be adequate to prevent ischemia. Under these circumstances, closure of the defect with a decrease in pulmonary arterial pressure is catastrophic.

The right coronary artery is greatly dilated, and large collaterals may be visible on the surface of the heart. The left coronary artery is seen entering the main pulmonary artery, usually into the left pulmonary sinus, but rarely enters a branch pulmonary artery. It is usually only 2 to 5 mm long before it branches.

In infancy, the heart is large, with the left ventricle and atrium in particular being dilated and hypertrophied. The anterolateral papillary muscle may be atrophic and scarred, and the chordae attached to it may be shortened. In some studies, the posterior papillary muscle has been similarly affected (33). There may be diffuse endocardial fibroelastosis of the left ventricle, and the anterior mitral valve leaflet is

often thickened. Thinning and scarring of the anterolateral left ventricular wall and apex owing to infarction are noted, and there are often mural thrombi.

In adults, the left coronary artery is thin-walled, resembling a vein. The heart is usually enlarged, but relatively not as much as in infants, and there is usually no endocardial fibroelastosis. However, there is usually scarring and calcification of the anterolateral papillary muscle and occasionally even of the adjacent left ventricle (18,34).

Clinical Features

For infants, the description by Bland et al. (32) still applies:

Nothing remarkable was noted about the patient until the tenth week; while nursing from the bottle, the onset of an unusual group of symptoms occurred which consisted of paroxysmal attacks of acute discomfort precipitated by the exertion of nursing. The infant appeared at first to be in obvious distress, as indicated by short expiratory grunts, followed immediately by marked pallor and cold sweat with a general appearance of severe shock. Occasionally, with unusually severe attacks, there appeared to be a transient loss of consciousness. The eructation of gas at times seemed to relieve the discomfort and to shorten the duration of the attack which usually lasted from 5 to 10 minutes, and following which the infant might proceed to nurse without difficulty and remain free of symptoms for several days.... It seems probable that in this infant, the curious attacks of paroxysmal discomfort... were those of angina pectoris. If this is true, it represents the earliest age at which this condition has been recorded.

These patients with angina can be misdiagnosed as having either colic or reflux. Not all infants present in this way. Many present with the signs and symptoms of congestive heart failure. A few children have severe difficulties in infancy and then gradually improve until they are asymptomatic. Older children and adults may be asymptomatic or may have dyspnea, syncope, or angina pectoris on effort. Sudden death after exertion has been common (35). However, typical myocardial infarctions or congestive heart failure are rare in adults.

On physical examination, there may be signs of congestive heart failure. In infants, the heart is usually enlarged, the left ventricle being the predominant ventricle affected. However, there may be right ventricular enlargement and a loud pulmonary component of the second heart sound if left ventricular failure has caused considerable pulmonary hypertension. The first heart sound may be soft or absent (if there is mitral regurgitation), and apical gallop rhythms are common. There may be no murmurs or they may have a murmur of mitral regurgitation. At times, there is a soft continuous murmur at the upper left sternal border that is similar to the murmur of a small patent ductus arteriosus, which is due to the continuous flow from the anomalous coronary artery into the pulmonary artery.

Electrocardiography

Classically, because there is an anterolateral infarct by the time the infant presents for diagnosis, there will be abnormal Q waves in leads I, aVL, and precordial leads V4 to V6. There also may be abnormal R waves or R-wave progression in the left precordial leads. Although this pattern is not pathognomonic for this anomaly (it is seen in myocardial infarcts from other causes or occasionally in cardiomyopathies), if it is found, the diagnosis of this anomaly should be considered and evaluated by other means. Even in asymptomatic adults, the resting electrocardiogram is abnormal, and abnormal ischemic responses occur with exercise (34).

Figure 32.6. Anomalous origin of the left main coronary artery from the pulmonary artery. **A:** In the fetus, both right and left coronary arteries receive forward flow from the great arteries. **B:** Early after birth, before collaterals are well developed, there may be an anterolateral infarct and slight retrograde flow from the left coronary artery to the pulmonary artery. **C:** After collaterals have enlarged, there is high flow in the enlarged right coronary artery and the collaterals and significant retrograde flow into the pulmonary artery. Arrows indicate direction and approximate magnitude of flow in the right and left coronary arteries and the collaterals between them. A, aorta; LAD, left anterior descending coronary artery; LCX, left circumflex coronary artery; P, pulmonary artery; RCA, right coronary artery.

Noninvasive Imaging

On the chest film in affected infants, there is marked cardiomegaly, predominantly of the left atrium and ventricle, and evidence of pulmonary edema. These features are similar to those of many forms of cardiomyopathy, with which this anomaly is often confused.

Nuclear myocardial perfusion imaging is quite sensitive, showing reduced uptake in the anterolateral ischemic region. However, this finding is not specific because it has been seen in cardiomyopathies as well.

Echocardiography with Doppler color flow mapping has replaced cardiac catheterization as the standard method of diagnosis (36). The improved resolution of current echocardiographic equipment often allows the abnormal attachment of the origin of the left coronary artery to be seen. Color Doppler interrogation shows that flow passes from the coronary artery into the pulmonary artery. Therefore, even if the attachment of the coronary artery to the great artery is uncertain by 2-D imaging, the presence of diastolic flow into the pulmonary artery will be informative. An enlarged right coronary artery should also raise suspicion of the diagnosis. The study also will show the size and function of the cardiac chambers, particularly the left ventricle as well as regional left ventricular wall motion abnormalities and mitral regurgitation. There may be increased echogenicity of the papillary muscle and adjacent endocardium due to fibrosis and fibroelastosis.

Computed tomography scans have shown high resolution for defining coronary artery anatomy and origination in most older patients. The main advantage of this technique is rapid acquisition times and, particularly with the 32- and 64-detector scanners, high resolution. However, ECG gating of the scans requires heart rates to be slow or, in the younger child, pharmacologically slowed. There remains a significant radiation exposure with this technique, but its ability to define coronary artery abnormalities is excellent (Fig. 32.4) (see Chapter 11).

Cardiac Catheterization and Angiography

Although previously, cardiac catheterization and angiography were commonly used in the diagnosis of congenital coronary abnormalities, currently they are used only if the results of noninvasive imaging are uncertain. In symptomatic infants, diagnostic cardiac catheterization demonstrates a low cardiac

output and high filling pressures and usually some degree of pulmonary hypertension. In asymptomatic older patients, output and pressures are usually normal, except for a slight increase in left ventricular end-diastolic pressure. There may be a left-to-right shunt at the pulmonary arterial level, but because the shunt may be small, its absence does not rule out the diagnosis. Ventriculography demonstrates the dilated left ventricle and atrium with dysfunction of the anterolateral left ventricular free wall and the presence and severity of mitral regurgitation. Aortic root angiography will show the dilated right coronary artery and, if there are large collaterals, will show filling of the left coronary artery and passage of contrast material from the left coronary to the main pulmonary artery. Although main pulmonary arterial angiography may show reflux of contrast medium into the origin of the left coronary artery, neither this nor left ventriculography can reliably exclude the diagnosis.

Natural History

Of all children born with this rare anomaly, approximately 87% present in infancy (33), and of these, 65% to 85% die before 1 year of age from intractable congestive heart failure (37), usually after 2 months of age. A few children improve spontaneously (38). Others never have symptoms, perhaps because of extensive collaterals and even a restrictive opening between the origin of the left coronary artery and the pulmonary trunk. Nevertheless, even these people are at high risk of sudden death (35), especially during exercise. Some present as adults with exercise-induced angina (34) or with congestive heart failure owing to mitral regurgitation (18).

Treatment

The first effective surgical treatment was ligation of the left coronary artery at its origin from the pulmonary artery to prevent the steal. Most older children benefit from this procedure, especially if they have extensive coronary-to-pulmonary arterial shunting, but late sudden death can still occur (34,39).

Ligation of the origin of the left coronary artery and reconstitution of flow through it with an internal mammary arterial or saphenous venous graft has been successful (40,41), although graft thrombosis and stenosis has occurred, particularly with vein grafts. Late obliterative changes in saphenous

vein grafts have been seen (41), which can seriously complicate the patient's course because by approximately 3 years after successful revascularization, there is usually marked reduction of collaterals from the right coronary artery (16). Grafts using the internal mammary artery have a longer survival and are preferred when coronary reimplantation cannot be done.

Direct reimplantation of the origin of the left coronary artery into the aorta (with a button of pulmonary artery around the origin) has been proven successful and is considered the standard approach in many centers (42–45). An alternative approach is the Takeuchi et al. (46) procedure, in which an aortopulmonary window is created and a tunnel is fashioned that directs blood from the aorta to the left coronary ostium.

In the past, it was recommended that, because surgical mortality is high in the sickest infants, surgery should be delayed until after 18 to 24 months of age (47). More recently, as surgical experience has accrued, early surgical intervention to establish a two-coronary system has been found to have significantly improved outcomes (45,48). However, because of papillary muscle infarction and dysfunction, significant preoperative mitral insufficiency has been found to be a risk factor for both mortality and need for late mitral valve surgery. Additionally, it has been reported that a two-vessel repair is feasible even in the sickest infants if postoperative support with a left ventricular assist device is used (49).

RARE CORONARY ANOMALIES

Coronary Atresia

Total absence of the extramural coronary arteries is rare and occurs most often with pulmonary atresia and aortic atresia. In both these anomalies, pressure in the small but hypertrophied right or left ventricle is at or above aortic pressure and enlarged sinusoids carry blood from the ventricle to be distributed in the distal coronary arterial branches.

Stenosis or Atresia of a Coronary Ostium

Stenosis or atresia of the ostium or first few millimeters of the left main coronary artery is one of the rarest of the congenital coronary anomalies. The more distal branches are normal and develop multiple collaterals from the right coronary artery. Patients may present from 3 months to 60 years of age with sudden death, angina pectoris, myocardial infarction, or congestive heart failure.

All Coronary Arteries from Pulmonary Artery

Rarely, both right and left coronary arteries, or a single coronary artery, comes from the pulmonary trunk. Unless there is a cardiac lesion causing pulmonary hypertension, these children do not survive infancy without surgical intervention. More recently, these rare patients who have had dual coronary surgical reimplantation have survived (50).

Left Anterior Descending Coronary Artery from the Pulmonary Artery

This is a very rare anomaly (18), with few patients having been described. Apart from a 7-month-old child who died with an anterior myocardial infarct, all the others have been 18 to 55 years of age. Five had angina pectoris, one an anterior myocardial infarct, and one had mitral regurgitation from papillary muscle dysfunction. Precordial murmurs were

common. Most had electrocardiographic evidence of ischemia. Chest radiographs were normal in three and showed cardiomegaly in three. Angiography was diagnostic. Echocardiographic findings have not been reported. Surgical treatment by ligation of the anomalous artery or connecting it to the aorta has been recommended (18).

Left Circumflex Coronary Artery from the Pulmonary Artery or Branches

A few of these anomalies have been reported (18), and in many patients, the circumflex coronary artery was attached to a branch pulmonary artery rather than to the main pulmonary trunk. All have been in children, and all but one had other congenital cardiac lesions.

Right Coronary Artery from the Pulmonary Artery

This anomaly is rare, only about one-tenth as common as the left main coronary artery coming from the pulmonary artery (17,31,33). The anomaly was initially known only as an incidental finding at autopsy (18), but recently, it has been associated with ischemia, syncope, cardiomyopathy, and sudden death (51,52).

Diagnosis

There may be a continuous murmur at the left sternal border. The electrocardiogram and chest radiograph are usually normal. Echocardiography with Doppler examination or cineangiography demonstrates the abnormal attachment of the right coronary artery to the pulmonary trunk and the retrograde flow from the right coronary artery to pulmonary artery. If echocardiography is nondiagnostic, definitive imaging of the anomalous right coronary artery origin can be obtained by computed tomography scan (28) or from angiography using the left coronary artery to fill the right by collaterals.

Treatment

Because most patients are asymptomatic and remain so, there is no way to determine which patients are at risk of dying without surgical correction of this defect. Nevertheless, because sudden death is a risk, many cardiologists recommend surgical correction, which has been done by reimplanting the right coronary artery into the aortic root (51).

MISCELLANEOUS ANOMALIES

Myocardial Bridges

The large epicardial coronary arteries run on the surface of the heart, with only their terminal branches penetrating the muscle, but it is very common for part of the epicardial artery to dip beneath the epicardial muscle for several millimeters so that there is a muscle bridge over the large artery (53). Most of these bridges are not functionally important, particularly if they are superficial. There are, however, documented examples of myocardial ischemia (54) or infarction associated with these bridges, including relief of ischemia after myotomy. During coronary angiography, a portion of the coronary artery appears to be narrowed in systole but widely patent in diastole, distinguishing it from a partially occlusive lesion of the artery (53).

Because myocardial bridges are so common and do not necessarily indicate present or future coronary arterial disease, the decision about myotomy to relieve anginal symptoms must

carefully be made. Not only should there be a well-defined muscle bridge, but there should be ischemia, based on electrocardiography or documented by nuclear scan or stress echocardiography, in the region supplied by the artery with the bridge. Ischemia may be due to long, thick bridges that compress the artery and relax unusually slowly, so that diastolic filling of the coronary artery beyond the bridge is impaired. Under these circumstances, disappearance of symptoms and of signs of ischemia may follow myotomy (54).

Although myocardial bridges causing ischemia are rare in children with normal hearts, they may represent a significant cause of morbidity and mortality in children with hypertrophic cardiomyopathy (see Chapter 54) (55), although this is also debated. Myocardial bridges with hypertrophic cardiomyopathy have been associated with chest pain, exercise intolerance, ventricular arrhythmias, and cardiac arrest in some, but debated in other studies (5,56). Unroofing the myocardial bridge has been reported to reduce the incidence of sudden death and arrhythmias in these patients (55). Children with hypertrophic cardiomyopathy and the above symptoms should be evaluated for bridges by stress perfusion imaging and selective coronary arteriography, and consideration should be given for unroofing the bridges if detected and felt to be causative.

CORONARY ARTERY PATTERNS WITH CONGENITAL HEART DEFECTS

Complete Transposition of the Great Arteries

Anomalies of the coronary arteries in transposition of the great arteries are important to identify because some patterns have been more difficult to transfer with the arterial switch operation. Anomalies occur in both the origin and distribution, with further anomalies secondary to intramural coursing of some vessels. This topic is briefly reviewed in this chapter, and a more complete review can be found in Chapter 49.

Terminology of the anomalies has been controversial because the aorta and main pulmonary artery are abnormally related in complete transposition of the great arteries and the aortic sinuses do not have their normal positions. The two sinuses adjacent to the pulmonary artery are termed facing sinuses (57). The nomenclature of the facing sinuses depends on the relationship of the great vessels. If the vessels are side by side, then the sinuses are termed anterior or posterior. If the great vessels are oblique, the sinuses are left anterior or right posterior. If the vessels are anterior-posterior, the sinuses are right or left (57).

The presence of a ventricular septal defect or of side-by-side great vessels should alert the cardiologist to an increased likelihood of coronary anomalies. In almost all patients, the coronary arteries arise from the facing sinuses (57,58). In 60%, the coronary arteries come from their appropriate sinuses and branch normally, a pattern seen most often with the aorta anterior and to the right of the pulmonary artery. The coronary arteries usually take the shortest course to reach their distribution, and because the aorta is anterior, the left main and circumflex coronary arteries pass anterior and leftward to the RVOT (Fig. 32.7A). The next most common variation is the left circumflex arising from the right coronary artery and coursing posterior to the pulmonary artery, which is seen in about 20% of patients, usually with side-by-side great vessels (Fig. 32.7B). The coronary arteries also may be completely inverted, with the right coronary artery arising from a left anterior sinus and the left coronary artery arising from the right posterior sinus (Fig. 32.7C). The coronary vessels also may be partially inverted, with the left circumflex arising from

Figure 32.7. Coronary arteries in complete transposition of the great arteries. **A:** Most common variant (60%). **B:** Next most common variant, with left circumflex coronary artery (LCX) coming from the right coronary artery (RCA) (20%), which is seen most often with side-by-side great arteries. **C:** Inverted arteries coming from the inappropriate sinuses (4%). **D:** Inverted arteries with the left anterior descending coronary artery (LAD) coming from the right coronary artery (RCA) (4%). Variants with single (8%) and intramural (5%) coronary arteries are not illustrated. A, aorta; LMCA, left main coronary artery P, pulmonary artery.

the right posterior sinus and the left anterior descending arising with the right coronary artery from the left anterior sinus (Fig. 32.7D).

Finally, various single coronary anomalies may occur, and intramural coursing of any of the variants may occur, usually with branches passing between the great vessels. These variations affect the planning and conduct of the arterial switch operation because it may be difficult to move the coronary arterial origins to the neo-aortic root without creating excessive tension.

Tetralogy of Fallot

About 40% of tetralogy patients have an abnormally long, large conus artery that supplies a significant mass of myocardium. In 4% to 5%, the left anterior descending coronary artery arises from the right coronary artery and passes across the RVOT (Fig. 32.2F) (59). Occasionally, a single coronary artery comes from either the right or left sinus and the major branch that crosses the heart may pass across the RVOT (Fig. 32.4C,F) or pass behind the aorta and so avoid the outflow tract (Fig. 32.4B,E). Rarer variations also occur (33,59).

If major arteries cross the RVOT, it makes surgery with the traditional transannular incision more difficult. To avoid cutting the artery and infarcting part of the myocardium supplied by it (60), the surgeon may make incisions parallel to the artery, make incisions above and below the artery, tunnel underneath the artery, or bypass the stenotic region with a conduit (59). All these approaches interfere with the effectiveness of the surgery and in the small infant

may lead to the decision to palliate rather than perform a total repair.

These anomalies may be detected by echocardiography and if the anatomy is uncertain, aortic root angiography or selective coronary angiography is necessary (59). Although the surgeon can usually see the anomalies, there are advantages in knowing about them in advance to plan the procedure more effectively. Furthermore, the anomalous arteries may not be visible if they are obscured by epicardial adhesions from previous surgery or if they run deep in the myocardium.

Congenitally Corrected Transposition of the Great Arteries (L-Transposition)

The aorta is anterior and to the left of the pulmonary artery, and the two main coronary arteries come from the facing sinuses as seen with D-transposition of the great arteries. The anterior sinus is usually the noncoronary sinus. Because of this anatomy, there is some confusion about naming coronary arteries that appear to arise from incorrect sinuses (58,61). Some describe the vessels as right or left sided, based on their sinus of origin (61), whereas others (62) describe the arteries based on their territory of supply, and that terminology is used here. The left coronary artery supplies the left ventricle but arises in the right facing sinus. It passes in front of the pulmonary annulus and divides into left anterior descending and circumflex branches, the latter passing in front of the right atrial appendage in the atrioventricular groove. The right coronary artery supplies the systemic right ventricle. It arises from the left facing sinus and runs in the atrioventricular groove in front of the left atrial appendage to terminate as the posterior descending artery. The most common variant is a single coronary artery coming from the right facing sinus.

Double-Inlet Left Ventricle (Univentricular Heart)

Because there is no true ventricular septum and there is no typical interventricular groove, the arterial branches that run along the borders of the rudimentary outlet chamber are referred to as delimiting arteries (33,63) rather than as anterior descending arteries.

When the outlet chamber is anterior and to the right, the aorta and pulmonary artery are related as in complete transposition. The right coronary artery arises from the right facing aortic sinus and runs along the right atrioventricular sulcus. The left main coronary artery comes from the left facing sinus and continues around the left atrioventricular groove as the circumflex artery. The left and right coronary arteries give off the left and right delimiting arteries, respectively. When the outlet chamber is anterior and to the left, the great vessels are related like those in congenitally corrected transposition of the great arteries (CCTGV) (L-transposition). The right and left main coronary arteries arise from their respective facing sinuses, and the "anterior descending" coronary artery may come from the left or the right coronary arteries or there may be two delimiting arteries that border the rudimentary outlet chamber (63). With any of these variants, there may be several large diagonal arterial branches that run parallel to the delimiting branches and cross the outflow tract of the right ventricle, making septation difficult.

Double-Outlet Right Ventricle

The coronary artery origins are usually normal in most forms of this group of anomalies, but because the aortic sinuses are rotated clockwise, the right coronary artery arises anteriorly and the left coronary artery arises posteriorly (58). When the

aorta is anterior and to the right, the coronary pattern is similar to that in CCTGV, with the right coronary artery arising from the right facing sinus. In 15%, there may be a single coronary artery arising anteriorly or posteriorly (64). Occasionally, the left anterior descending coronary artery comes from the right coronary artery and crosses the RVOT, as in tetralogy of Fallot (64). When the aorta is to the left, the right coronary artery passes to the right from the anterior sinus of the leftward aorta in front of the pulmonary artery to reach the atrioventricular groove.

Truncus Arteriosus

The right and left coronary arteries usually arise normally from their appropriate sinuses (65). If, however, the valve has more than three cusps, conventional descriptions must be abandoned. What is most consistent is that the left main coronary artery arises from the posterior sinus. Major variants include unusually high ostia, closely approximated ostia, or a single ostium (65). Large diagonal branches of the right coronary artery may cross over the anterior surface of the right ventricle and contribute to flow to the ventricular septum and even part of the left ventricular free wall (65).

CONGENITAL ANOMALIES OF THE AORTIC ROOT

Aortic–Left Ventricular Defect (Tunnel)

This rare lesion is a vascular connection between the aorta and the left ventricle (Fig. 32.8). Some describe it as a tunnel that begins above the right coronary ostium, usually separated from it by a ridge, and passes behind the right ventricular infundibulum and through the anterior upper part of the ventricular septum to enter the left ventricle just below the right and left aortic cusps (66). It is usually short and direct but may be aneurysmal. Levy et al. (66) attributed the tunnel to a congenital endothelialized connection between the aorta and

Figure 32.8. Aortic–left ventricular tunnel. Sagittal section showing the tunnel burrowing through the septal wall to enter the left ventricle. The proximal opening of the tunnel is superior to the right coronary ostium. LV, left ventricle; RCA, right coronary artery; RV, right ventricle.

the left ventricle. Others (67) have considered the lesion to be a congenital defect associated with the thinned-out anterior wall of the left ventricular outflow tract where the right aortic sinus meets the membranous septum.

Many of these patients present in infancy with congestive heart failure. They have signs resembling marked aortic valve regurgitation: a wide pulse pressure with a low diastolic blood pressure, a hyperactive dilated left ventricle and enlarged left atrium, and a loud to-and-fro murmur at the base. The electrocardiogram shows varying degrees of left ventricular and atrial hypertrophy. The chest radiograph shows variable cardiomegaly, possibly signs of congestive heart failure, but in all patients there is a dilated ascending aorta and in some a bulge of the enlarged right aortic sinus. Echocardiography with Doppler color flow mapping and aortography serve to separate this lesion from aortic valve regurgitation by the absence of retrograde flow through the aortic valve, from a coronary artery–left ventricular fistula by the finding of normal right and left main coronary arteries, from an associated ventricular septal defect by the absence of a left-to-right shunt through the defect, and from a ruptured sinus of Valsalva by the anterior position of the tunnel and the absence of a dilated sinus of Valsalva (68). Treatment has been surgical, but there is a high incidence of aortic incompetence after surgery. Alternative treatment options include transcatheter occlusion in selected patients.

Aneurysms of the Sinus of Valsalva

A localized weakness of the wall of a sinus of Valsalva, a relatively rare lesion reported in the 19th century (69), leads to aneurysmal bulging and even rupture. It is to be distinguished from diffuse dilation of all the sinuses as is seen in Marfan syndrome. The localized aneurysms are usually congenital, with thinning just above the annulus at the leaflet hinge owing to absence of normal elastic and muscular tissue (70). These aneurysms can follow infective endocarditis. At times, deciding if the endocarditis is the cause or the consequence of the aneurysm is impossible.

Pathologic Anatomy and Physiology

About 75% of the patients are male. Two-thirds of the aneurysms are located in the right aortic sinus, one-fourth in the noncoronary sinus, and the rest in the left aortic sinus (71). The aneurysms may be isolated or in 30% to 50% may be associated with ventricular septal defects, especially defects of the outlet septum. The proportion of patients with ventricular septal defects is higher when the aneurysm arises from the right sinus. With an associated ventricular septal defect, particularly if subpulmonic, there is often prolapse of the aortic valve cusp and aortic incompetence. The aortic incompetence tends to be progressive as the valve prolapses farther and becomes fibrous and stiff. Coarctation of the aorta, atrial septal defect, tetralogy of Fallot, and patent ductus arteriosus also may be associated with these aneurysms. Because the aortic root is central, the aneurysms can rupture into any cardiac chamber, and virtually all combinations of sinus and chamber fistulas have been described. Rupture is most often of the right sinus aneurysm into the right ventricle, particularly if there is an outlet ventricular septal defect. The next most frequent site of rupture is into the right atrium from an aneurysm in the noncoronary sinus. Rupture into the pericardium is rare. At surgery, most fistulas resemble wind socks projecting from the sinus into the chamber of entry, with one or more openings near the end of the wind sock.

These aneurysms do not always rupture but may cause symptoms by obstructing the RVOT, distorting the aortic valve and causing aortic incompetence, compressing the left

coronary artery and causing myocardial ischemia, or causing conduction disturbances or even complete heart block by compressing the conduction system. Because all complications of these aneurysms are functions of their size, and because they grow slowly, they seldom present in infancy and early childhood. The mean age for the onset of symptoms owing to sudden rupture of the aneurysms was 31 years (71). Rupture can follow acute chest trauma or severe exertion.

If the aneurysm ruptures, the size of the fistula determines the amount of shunting and its site of entry into the heart often determines its specific features. Thus, aneurysmal rupture into the left heart does not produce signs of a left-to-right shunt, whereas rupture into the right heart produces a left-to-right shunt of variable size.

Infective endocarditis is an important complication of the smaller fistulas. It may occur in 5% to 10% of patients with these congenital aneurysms (71).

Clinical and Laboratory Features

Before rupture, these aneurysms are diagnosed only incidentally during imaging for other lesions (72). Rupture may be accompanied by a tearing pain in the chest or upper abdomen. If a huge shunt develops rapidly, the symptoms of congestive heart failure appear almost immediately, but with smaller fistulas, it may take several months for heart failure to develop (71). About 20% of patients are asymptomatic.

With a small fistula, there may be only a continuous murmur like that of a ductus arteriosus, but with its maximal intensity in the third or fourth intercostal space near the sternal edge. If the fistula enters the right atrium, the murmur may be maximal to the right of the sternum. With larger fistulas, there will be a wide pulse pressure, a collapsing pulse, and left ventricular hyperactivity. If the fistula enters the right side, there will be right ventricular hyperactivity as well. A large fistula entering the left ventricle may display a to-and-fro murmur and simulate aortic incompetence. Occasionally, there is only a diastolic murmur in fistulas entering the left ventricle (71) or the high-pressure right ventricle in a neonate. If a ventricular septal defect is present, especially with infundibular obstruction, the combined murmurs can be confusing.

With a large chronic fistula, the electrocardiogram will show hypertrophy of the appropriate chambers. Occasionally, signs of myocardial ischemia or conduction defects occur because of compression of the coronary artery or the conduction system.

The chest roentgenogram will show enlargement of the appropriate chambers as well as pulmonary overcirculation if there is a large left-to-right shunt. Evidence of congestive heart failure may be seen. The aortic root is not enlarged, although in the rare aneurysms of the left sinus of Valsalva there may be a bulge on the left aortic root border.

Two-dimensional echocardiography with Doppler color flow mapping shows the aneurysmal dilation, even before rupture (73), but transesophageal echocardiography may give information not obtainable by routine transthoracic echocardiography (74), including information on degree and mechanism of associated aortic insufficiency. Further noninvasive imaging with computed tomography or magnetic resonance scans has been shown to provide excellent definition of the aneurysm and the tissue planes involved (75).

Cardiac Catheterization and Angiography

Previously, cardiac catheterization was used for diagnostic purposes in this entity, to define the magnitude of any left-to-right shunt, ventricular systolic and diastolic pressures, pulmonary hypertension, and any infundibular obstruction. However, its diagnostic use has been largely supplanted by

noninvasive imaging with CT or MRI. More recently, in highly selected cases, percutaneously delivered devices have been used to occlude the ruptured aneurysm (76), but caution must be advised so as to not cause future aortic valvar insufficiency by the device.

Management

While previously, some authors have advocated treatment of congestive heart failure, with emphasis on afterload reduction to minimize runoff through the fistula, current definitive therapy is surgical anatomic correction.

Paul M. Weinberg ■ Shobha Natarajan ■ Lindsay S. Rogers

Congenital abnormalities of the aortic arch have been known at least since the anatomical reports of anomalous right subclavian artery by Hunauld (1) in 1735, double aortic arch by Hommel (2) in 1737, right aortic arch by Fioratti and Aglietti (3) in 1763, and interrupted aortic arch by Steidele (4) in 1788. While the clinicopathologic correlation of swallowing difficulty with anomalous right subclavian artery was made by Bayford (5) in 1789, it was not until the 1930s and the use of barium esophagography that some arch anomalies were diagnosed during life. Since that time, clinical interest has generally paralleled surgical capability. The first division of a vascular ring was performed by Gross (6) in 1945, and the first successful repair of interrupted aortic arch was accomplished by Merrill et al. (7) in 1957. In the current era with the advent of minimally invasive surgery (8,9) and robotically assisted surgery (10), precise definition of aortic arch anatomy, preferably by noninvasive means, is essential.

ANATOMICAL CLASSIFICATION

Aortic arch anomalies can be thought of as falling into one or a combination of the following anatomical categories: abnormalities of branching, abnormalities of arch position including right aortic arch and cervical aortic arch, supernumerary arches including double aortic arch and persistent fifth aortic arch, interrupted aortic arch, and anomalous origin of a pulmonary artery branch from the ascending aorta or from the contralateral pulmonary artery branch.

LEFT AND RIGHT ARCH DEFINITION

Left and right aortic arch refer to which bronchus is crossed by the arch, not to which side of the midline the aortic root ascends. This is particularly important to remember when looking at projection images from angiography where it may be difficult to make the determination directly without significant cranial angulation. Practically, the sidedness of the aortic arch is usually determined indirectly with echocardiography or angiography by the branching pattern of the brachiocephalic vessels. As a rule, the first arch vessel contains the carotid artery opposite the side of the arch. However, caution must be exercised in using this indirect method, particularly when surgical decisions, such as the approach to repair of esophageal atresia, hinge on this determination. Three very rare anomalies are categorical exceptions to this rule: retroesophageal innominate artery, isolated innominate artery, and congenital absence of the carotid artery contralateral to the arch. But by far the most common source of error in the use of this rule is when it is difficult to decide which of two carotid arteries is the *first*. A more reliable rule, but one that may be difficult to apply with ultrasound imaging, is that retroesophageal vessels and

isolated vessels, that is, arising only from a ductus or ligamentum (without connection to the aorta), are *always* opposite the side of the aortic arch. Magnetic resonance imaging (MRI) or computed tomography (CT) shows the relationship of the arch to the trachea and bronchi *directly*, thus eliminating ambiguity when atypical branching patterns are encountered.

Embryology

The specific anomalies can better be understood through an appreciation of their embryologic origins. Development of the aortic arch system can best be described as a sequential appearance and persistence or dissolution of six paired vessels connecting the trunco-aortic sac of the embryonic heart tube with the paired dorsal aortae, which fuse to form the definitive descending aorta. Each arch corresponds to a branchial pouch derived from embryonic foregut. While the mechanism for determining persistence or dissolution of aortic arch components is not completely known, migration of neural crest cells into the pharyngeal arches (11) may play a significant role. In addition, the association of various arch anomalies such as right aortic arch, cervical aortic arch, aberrant and isolated subclavian or innominate arteries, and certain vascular rings, with microdeletions of chromosome 22q11 (12) implies a genetic component to the derivation of at least some arch anomalies. The fact that neural crest cells are also involved in development of the conotruncus and that conotruncal anomalies also occur in chromosome 22q11-deleted patients provides a further etiologic link to aortic arch anomalies.

The normal left aortic arch as shown by Congdon (13) is derived from the aortic portion of the embryonic truncus arteriosus, the left branch of the trunco-aortic sac, the left fourth arterial arch, the left dorsal aorta between the fourth and sixth embryonic arches, and the left dorsal aorta distal to the sixth arch. The three brachiocephalic branches of the arch are derived from the following: the innominate artery from the right branch of the trunco-aortic sac with the right common carotid artery from right third embryonic arch and right subclavian from right fourth arch and (proximal) right dorsal aorta proximally and right seventh intersegmental artery distally; left carotid artery from left third aortic arch; and left subclavian artery from left seventh intersegmental artery. While the appearance and loss of vessels as arches or portions of the brachiocephalic vasculature is sequential, Edwards (14) proposed the concept of a "hypothetical double aortic arch" that is, in essence, the potential contribution of nearly all embryonic arches to components of the definitive arch system. These diagrams are used extensively in the excellent monograph by Stewart et al. (15). They are invaluable not only to demonstrate possible embryologic explanations for each arch anomaly but also to help the diagnostician determine possible and probable arch anomalies and their corresponding sequences of arch vessels. We have adopted a simplified schematic version of the Edwards diagrams, which is feasible for those who are less

Figure 33.1. Totipotential aortic arch from embryonic contributions. D Ao, descending aorta; Dors Ao, dorsal aorta(e); E, esophagus; LPA, left pulmonary artery; RPA, right pulmonary artery; T, trachea; TA Sac, truncus aortic and pulmonary components; III, IV, VI refer to third, fourth, sixth embryonic arches, respectively, 7 IS, seventh intersegmental artery. artistically inclined, to provide similar information (Fig. 33.1). This can easily be drawn at the bedside or in the patient chart to diagram almost any arch anomaly and is used throughout this chapter to illustrate many of the abnormalities.

Diagnostic Methods

Beginning in the 1930s, barium esophagography was the primary method for diagnosing arch anomalies. In the 1960s and 1970s, angiography became the gold standard and remained so even in the face of echocardiography. While the branching pattern may be determined by careful examination of arch vessels in the suprasternal short- and long-axis views (16), arch sidedness is often inferred from the branching pattern and in some cases may be inconclusive or even lead to erroneous deduction. However, in the last 20 years, MRI and CT, where available, have supplanted angiography as the gold standard for definitive diagnosis of arch anomalies. Both modalities have the advantages of large fields of view and simultaneous visualization of vessels and airways, and both are minimally invasive. While CT usually has shorter scan times, that advantage is disappearing as MRI sequences become faster. MRI has the advantage of no ionizing radiation—still a significant problem with CT even with the reduced dosage strategies employed in some centers. Furthermore, MRI has capabilities for physiologic measurements, which are particularly helpful in patients with associated intracardiac disease.

There is still a role for ultrasonography in the diagnosis of arch anomalies, and, in particular, vascular rings. That is in the fetus where the fluid-filled trachea does not hamper visualization the way the air-filled trachea does after birth. Furthermore, the ductus arteriosus is virtually always patent, so that nearly all rings can be seen completely encircling the trachea with blood-filled vessels. Specific strategies for recognizing vascular rings in the fetus have been reported by several authors (17–19).

However, one study (20) found a different distribution of rings in fetuses (predominantly diverticulum of Kommerell) from what has been observed by others postnatally (predominantly double aortic arch), and with most of the fetal-diagnosed cases being asymptomatic through infancy.

CLINICAL CLASSIFICATION

In addition to the anatomic categorization of aortic arch anomalies discussed above, one can subdivide arch anomalies according to clinical features as follows: vascular rings; nonring vascular compression of the trachea, bronchi, or esophagus; noncompressive arch malformations; and ductal-dependent arch anomalies including interrupted aortic arches and isolated subclavian, carotid, or innominate arteries. In addition, genetic syndromes represent an important group of patients from the standpoint of diagnostic criteria and associated abnormalities.

Chromosome 22q11.2 Deletion Syndromes

Chromosome 22q11.2 microdeletions are seen in more than 80% of patients with DiGeorge, velocardiofacial, and conotruncal anomaly face syndromes. The combination has been referred to collectively with the acronym CATCH 22 (Cardiac defects, Abnormal facies, Thymic hypoplasia, Cleft palate, and Hypocalcemia together with microdeletion of chromosome 22) (21). Most of these patients have conotruncal anomalies: either subaortic stenosis with posterior malalignment of the infundibular septum, often associated with interrupted aortic arch, type B; truncus arteriosus communis; or tetralogy of Fallot, with or without pulmonary atresia. More than two-thirds of these have aortic arch anomalies (22). What is more, nearly one-fourth of patients with arch anomalies but without intracardiac defects have 22q11 deletion (23). While a wide variety of arch anomalies has been noted in these patients, there is a predilection for anomalies involving absence of one or both embryonic fourth aortic arches, as seen most notably in abnormalities of the subclavian arteries: aberrant, isolated, or cervical origin (22,24,25). When all three types of subclavian artery anomaly are included, more than 80% of patients with both conotruncal and arch anomalies involving the subclavian artery have 22q11 deletion compared to only 17% of patients with conotruncal anomaly and normal subclavians (24). Other fourth arch anomalies occurring in chromosome 22q11 deletion syndromes include type B interrupted aortic arch, cervical aortic arch with separate origins of internal and external carotid arteries from the arch (26), and possibly “stenosis” in the middle of the right aortic arch between right carotid and subclavian arteries along with a diverticulum of Kommerell (27). The pathogenesis of these fourth arch anomalies may be mediated by transforming growth factor- β 2 (TGF- β 2) as demonstrated in TGF- β 2 knockout mice (28,29).

Vascular Rings

A vascular ring is an aortic arch anomaly in which the trachea and esophagus are completely surrounded by vascular structures. The vascular structures need not be patent, for example, a ligamentum arteriosum or atretic segment of aortic arch may complete a ring. The clinical picture typically includes stridor, though pneumonia, bronchitis, or cough may characterize the presentation. Infants may demonstrate a posture of hyperextension of the neck. Less commonly, patients exhibit reflex apnea associated with eating. A common history is that of a 1- to 3-month-old with “noisy breathing since birth” who develops more significant respiratory distress in association with an intercurrent upper

TABLE 33.1

Three “D”s Indicating Vascular Rings When Not All Vessels Are Patent

<ul style="list-style-type: none"> ■ Diverticulum ■ Dimple ■ Descending aorta 	}	Opposite the side of the arch
--	---	-------------------------------

respiratory infection. Less commonly and usually in toddlers or older children, the presentation will be swallowing difficulty or choking on food. These patients tend to have looser rings, but careful questioning of parents will sometimes reveal the history of stridor in infancy, which was passed off as “recurrent bronchitis.” Some infants will have wheezing and may be mistaken for having asthma or bronchiolitis. In general, such patients will have normal oxygen saturations and in severe cases, elevated $p\text{CO}_2$, whereas patients with bronchiolar obstruction will tend to have hypoxemia with normal $p\text{CO}_2$ (30). Some asymptomatic patients will be discovered incidentally while imaging for another reason (31). Occasionally, in patients with associated intracardiac abnormalities, respiratory symptoms may mistakenly be attributed to the cardiac disease when, in fact, they are in part or completely due to the vascular ring. Older children and adults are occasionally followed for many years with a diagnosis of “asthma” only to have a vascular ring diagnosed and surgically treated with resolution of symptoms (32,33). However, respiratory symptoms may persist for months or years after surgical relief of the ring due to the presence of tracheomalacia. Fetal echocardiography is one such source of discovery of vascular rings. Many cases found by this modality may be asymptomatic after birth (20) but knowledge of the ring can lead to prompt treatment if symptoms do occur later (34). In general, asymptomatic patients do not require surgery, but if associated with congenital heart disease that requires surgery, it should be addressed at the time of the cardiac surgery. The diagnosis may be suspected from the combination of history and plain chest film; however, if symptomatic, the patient should have definitive study.

When all elements of the ring are patent, visualization, especially by tomographic imaging, is straightforward. In cases where the ring is completed by an atretic segment of aorta or ligamentum arteriosum, those segments cannot be visualized with current imaging technologies. However, these rings are recognizable by the presence of one of three “D”s *opposite* the side of the aortic arch: Diverticulum, Dimple, or Descending aorta (Table 33.1). A diverticulum is a large vessel arising from the descending aorta that gives rise to a smaller-caliber vessel or vessels with a *sudden* taper beyond the trachea and esophagus. A dimple is a small tapered, blindly ending outpouching from the aorta. Descending aorta opposite the side of the aortic arch refers to the location of the descending aorta in the upper thorax with a dramatic angulation between the transverse arch and descending aorta. (This is distinct from the typical right aortic arch that begins its descent on the right but in most cases gradually moves to the left by the point where it reaches the diaphragm.) These three “D”s *only* occur when connected by a ligamentum arteriosum or an atretic segment of aortic arch and *always* indicate a vascular ring.

NORMAL LEFT AORTIC ARCH AND VARIANTS

The normal left aortic arch crosses the left mainstem bronchus at the level of thoracic vertebra T5 and descends left of the midline to the diaphragm and beyond in cases of visceral situs solitus. The normal branching pattern has the right

innominate artery first, which, in turn, branches into right common carotid and right subclavian arteries, the left carotid artery second, and the left subclavian artery third. Typically, the ductus arteriosus or the ligamentum arteriosum joins the aorta distal to the takeoff of the left subclavian artery but can insert more proximally, as in some cases of tetralogy of Fallot.

There are two frequent variants of the left aortic arch. One is common brachiocephalic trunk, in which the right innominate and left carotid arteries arise from a single origin. This is present in 10% of otherwise normal left arches (35) and usually is of no consequence, although some have suggested that innominate artery compression of the trachea (discussed below) is more frequent when common brachiocephalic trunk is present. The other variant is separate origin of the left vertebral artery from the aortic arch proximal to the takeoff of the left subclavian artery rather than from the subclavian artery (Fig. 33.2A). This too is seen in 10% of normal left arches (35) and is important only in the fact that it should not be confused angiographically or echocardiographically with anomalous right subclavian artery in which there are also four brachiocephalic vessels (see below). The distinguishing feature here is the normal appearance of the first arch vessel (right innominate artery), being larger than the second (left carotid), and the third (left vertebral) being smaller than the fourth (left subclavian). Again, no functional significance attends this common variant.

Embryology

Using the totipotential aortic arch diagram (Fig. 33.1), one envisions the normal left arch resulting from dissolution of the right sixth aortic arch (ductus) and the right dorsal aorta distal to the origin of the seventh intersegmental artery (distal subclavian artery precursor). Thus the right fourth arch, rather than remaining an arch (connecting trunco-aortic sac to descending aorta), becomes the proximal right subclavian artery as it arises from the innominate artery. The left fourth arch becomes the definitive aortic arch.

ABNORMAL LEFT AORTIC ARCH

Left Aortic Arch with Retroesophageal Right Subclavian Artery

This anomaly was first described anatomically by Hunauld (1) in 1735. Bayford (5) linked the postmortem discovery of such a case with the history of swallowing difficulty during life and coined the term “dysphagia lusoria” (from the Latin, *lusus naturae*, trick of nature). This is the most common arch anomaly, occurring in 0.5% of the general population (demonstrated in a large adult autopsy series [36]). The incidence in Down syndrome patients with congenital heart disease is very high at 38% (37).

This is the most common form of anomalous or aberrant right subclavian artery (another is described below under left arch, right descending aorta) with the following branching pattern being usual: the first branch is the right carotid artery, the second the left carotid, third the left subclavian, and fourth a retroesophageal right subclavian artery arising from the posteromedial aspect of the distal aortic arch (Fig. 33.1). Of note is the fact that 20% of cases have a bicarotid trunk (i.e., common origin of both carotid arteries) and 14% have right vertebral origin from the right carotid so that the carotid artery bifurcates even though there is no innominate artery (38). Most cases of left aortic arch with retroesophageal right subclavian artery are asymptomatic, with the diagnosis made while imaging for another condition or at autopsy. In a large pediatric echocardiographic series (16), nearly one-third of patients with aberrant right subclavian artery

Figure 33.2. Normal left arch. **A:** Right posterior oblique view of 3-D shaded surface display from MRI of normal left aortic arch variant with separate origin of left vertebral artery (L Vert) from aortic arch. It shows origin of right innominate artery (R Innom), which gives rise to right carotid (RCA) and right subclavian (RSCA) arteries, left carotid (LCA), L Vert, and left subclavian (LSCA). Note the relatively short length of R innom and the relatively distant division of RCA into internal and external carotid arteries (*above arrow*). **B:** Presumptive embryonic arch diagram of normal left arch. *Dotted lines* indicate dissolution or disappearance of portions of embryonic arch system—right sixth arch and right dorsal aorta distal to right subclavian artery.

had no intracardiac abnormality, while 18% had conotruncal anomalies—especially tetralogy of Fallot and interrupted aortic arch, 11% had left-sided obstructive lesions such as hypoplastic left heart syndrome and coarctation, and 10% had common atrioventricular septal defect. In that study, the highest incidence of aberrant right subclavian artery amongst the various lesions was interrupted aortic arch at 28%, followed by hypoplastic left

heart syndrome at 10%, common atrioventricular septal defect at 8%, and tetralogy of Fallot with pulmonary atresia at 7%.

Embryology

This can be envisioned as a disappearance of the right fourth aortic arch (Fig. 33.3F). The distal right dorsal aorta (rather

Figure 33.3. Left arch, retroesophageal right subclavian artery. **A:** Anterior view of 3-D shaded surface display from MRI. Note that RCA is superimposed on RSCA in this view. **B:** RCA and RSCA separated in slightly right anterior oblique view showing sequence of arch vessels: RCA, LCA, LSCA, and RSCA.

Figure 33.3. (Continued) C: Posterior view. Note virtually uniform caliber of RSCA from origin to peripheral extent. D: Overhead view showing proximity of RCA and RSCA. A Ao, ascending aorta; D Ao, descending aorta; RCA, right carotid artery; RSCA, right subclavian artery; LCA, left carotid artery; LSCA, left subclavian artery. E: Barium esophagram showing small posterior indentation by retroesophageal subclavian artery. F: Presumptive embryonic arch diagram showing dissolution of right fourth and sixth aortic arches.

than the right fourth arch) becomes the proximal right subclavian artery forming its retroesophageal portion. The right sixth arch (ductus) also involutes.

Diagnosis and Management

Since there is no innominate artery, the first and second branches from the aortic arch, the right and left carotid arteries respectively,

tend to be similar in size as are the last two branches, the left and right subclavian arteries. Barium esophagography is usually specific for the diagnosis with a fixed filling defect usually slanting upward to the right and best appreciated with fluoroscopy. The defect is relatively small (Fig. 33.3E) compared to that seen in other anomalies where an aortic arch, or diverticulum, impinges on the esophagus (see Fig. 33.11). With angiography, the diagnosis may sometimes be missed in the anteroposterior

(AP) projection since the right subclavian may be superimposed on the right carotid artery in the usual position (Fig. 33.3A). However, careful single-frame analysis will demonstrate the earlier filling of the right carotid on an aortic root injection or the earlier filling of the right subclavian on a descending aortic injection. This arch anomaly is usually recognized with echocardiography by the branching pattern discussed above, namely, a nonbifurcating first branch that ascends toward the right, followed by two successive left-sided vessels (left carotid and left subclavian arteries), followed by a fourth branch that heads toward the right but may disappear behind the trachea. The retroesophageal course of the subclavian artery is shown by MRI on transverse (axial) cuts, and the largest expanse from aortic origin to the thoracic apex is usually seen on coronal sections.

Left Aortic Arch with Right-Sided Retroesophageal Diverticulum of Kommerell

This very rare arch anomaly was actually the first vascular ring to be diagnosed in life with barium esophagography by

Kommerell (39) whose name is associated with this diverticulum. Although, the name is usually used in reference to the much more common mirror image of this anomaly, viz., a left-sided diverticulum associated with a right aortic arch (discussed below). The branching pattern in left arch with retroesophageal diverticulum is identical to that of the more common left arch with retroesophageal right subclavian artery discussed above, which is not a vascular ring. The difference is in the caliber of the proximal subclavian artery (Fig. 33.1). The significance of this is that the abrupt change of vessel size always indicates the presence of a ligamentum arteriosum, which completes a vascular ring.

Embryology

This anomaly exhibits embryology similar to that of left arch, retroesophageal right subclavian artery described above, that is, involution of the right fourth aortic arch. The difference is that unlike the aforementioned anomaly, the right sixth (ductal) arch persists and completes the ring (Fig. 33.4C).

Figure 33.4. Left aortic arch, retroesophageal diverticulum of Kommerell. **A:** Anterior view of 3-D shaded surface display from MRI showing sequence of arch vessels arising from aorta: RCA, LCA, LSCA, and RSCA. Note that RSCA comes from diverticulum (Div) seen better in B. **B:** Right posterior oblique view. Note tapering of Div from aortic end to RSCA origin. Also note dimple (open arrow) at site of ligamentum arteriosum. **C:** Embryonic arch diagram. Note similarity to Figure 33.3F, but with addition of persistent arch VI (ligamentum arteriosum).

Left Aortic Arch with Right Descending Aorta and Right Ductus (or Ligamentum)

This is a rare arch anomaly, also known as circumflex aortic arch, with branching pattern similar to left arch with retroesophageal right subclavian artery. However the arch itself is retroesophageal; hence the right subclavian artery, while it may arise as the last arch vessel, that is, aberrant subclavian, is not retroesophageal (Fig. 33.1). The descending aorta is connected by a ductus or ligamentum to the right pulmonary artery (RPA) forming a vascular ring.

Embryology

The embryology of this anomaly, also similar to left arch with retroesophageal subclavian artery, can be thought of as

a disappearance of the right fourth aortic arch but with the distal left dorsal aorta forming the definitive distal aortic arch and passing retroesophageally to a descending aorta beginning to the right of the vertebral column (Fig. 33.5D). Thus the right seventh intersegmental artery arises from the right-sided descending aorta. There is also persistence of the right sixth (ductal) arch connecting the RPA portion of the trunco-aortic sac with the distal right dorsal aorta similar to the also rare left arch diverticulum of Kommerell (above).

Diagnosis and Management

This diagnosis can be suspected if a patient who presents with symptoms suggestive of a vascular ring has findings of a left aortic arch without evidence of a right aortic arch. Plain chest roentgenogram can show the left-sided arch and

Figure 33.5. Cervical left arch, right descending aorta. **A:** Right lateral view with slight cranial angulation of 3-D shaded surface display from MRI. Trachea (green) trapped by ligamentum arteriosum (not visualized) between D Ao and RPA (blue). **B:** AP view of same reconstruction showing arch extending above level of clavicles (grey). Hairpin appearance of cervical arch is seen through translucent rendering of left clavicle. **C:** Posterior view of same 3-D reconstruction. Circumflex aortic arch (open arrow) passes behind trachea and esophagus (not shown) to D Ao, from which arises a diverticulum (Div) that gives rise to RSCA and ligamentum arteriosum. **D:** Embryonic arch diagram showing dissolution of right fourth arch and left sixth arch and persistence of right sixth arch remnant, namely, right ligamentum (R Lig [VI]). Note similarity to Figure 33.4C but with right descending aorta instead of left. In both cases, the retroesophageal portion is derived from embryonic dorsal aorta.

the right-sided upper descending aorta, particularly in adults. The addition of barium esophagography can demonstrate the large posterior indentation from the retroesophageal aorta; however, the course of this vessel, upward to the left, is indistinguishable from the much more frequently occurring right aortic arch with retroesophageal diverticulum (see below). In both cases the upper descending aorta is right sided. While the aortic knob on chest roentgenogram would be left sided, this is not always evident, especially in infants with a prominent thymus. Angiography will show the course of the aorta from left arch to retroesophageal segment to right upper descending. The subclavian artery can be seen arising from the descending aorta as it turns from its transverse to more nearly vertical course. This pattern can also be demonstrated by MRI with the addition of direct imaging of the aortic position relative to the trachea. *While most vascular*

rings can be divided through a left thoracotomy, this type and the rare diverticulum of Kommerell noted above are usually approached by a right thoracotomy (40), so that the ligamentum can be reached, although a midline approach may also be employed.

Left Aortic Arch with Isolated Right Subclavian Artery

Another rare anomaly, isolated subclavian artery means that the subclavian artery arises only from the ductus arteriosus. As with the previous two anomalies, the left arch version is much less common than the right arch form. The branching pattern is right carotid artery, left carotid artery or bicarotid trunk, and left subclavian artery (Fig. 33.6). According to a recent case report and review of the literature (41), five of

Figure 33.6. Left aortic arch with isolated right subclavian artery. Shaded surface display from gadolinium-enhanced 3-D MRI dataset. **A:** Straight AP view showing left aortic arch. In this view, the right carotid (RCA) and right subclavian (RSCA) arteries are superimposed giving the false impression of a normal right innominate artery (compare with Fig. 33.3 with retroesophageal right subclavian). Aao, ascending aorta; Dao, descending aorta; LCA, left carotid artery; LSCA, left subclavian artery. **B:** Steep right anterior oblique view shows the separation between the RSCA and the RCA. Arrowhead shows dimple where right ligamentum arteriosum is attached. **C:** Steep left posterior oblique view better demonstrates the isolated right subclavian artery (RSCA) and right vertebral artery (R Vert) through which blood flows to the subclavian from the circle of Willis. **D:** Embryonic arch diagram showing ipsilateral loss of right fourth arch and dorsal aorta with persistence of ipsilateral sixth arch.

14 cases had D-transposition of the great arteries (15,42–45) (Fig. 33.1), five had no intracardiac anomaly (in two of those (42,46) the ductus remained patent) (15,47,48), two (including their own case with a patent ductus) had tetralogy of Fallot (49), and one each had ventricular septal defect (VSD) (50) and interrupted aortic arch (51).

Embryology

This occurs with dissolution of the right fourth arch and right dorsal aorta but persistence of the right sixth arch.

Diagnosis and Management

If the ductus remains patent with high pulmonary resistance, the subclavian and vertebral arteries are supplied from the pulmonary artery resulting in decreased oxygen saturation in the right arm compared with the head (earlobe) except in transposition when the arm saturation would be higher than the head. Assuming bilateral ductus, the left arm and lower body would be expected to have saturations similar to the right arm, whereas the head, receiving blood from the ascending aorta would be different. When the ductus closes, the subclavian is typically supplied by retrograde flow from the vertebral artery via the circle of Willis. When this occurs in the absence of other anomalies it may go unrecognized or may cause vertebral insufficiency with so-called congenital subclavian steal. In many cases, there may be no symptoms or simply absence of the right arm pulse. This may be recognized with angiography by delayed filling of the subclavian artery after aortic root injection. With phase-encoded velocity mapping, retrograde flow in the vertebral artery can be detected on MRI. Symptomatic patients are treated by implantation of the subclavian artery into the ipsilateral carotid artery or the aorta.

Left Aortic Arch with Cervical Origin of the Right Subclavian Artery

This rare anomaly was first reported by Kutsche and Van Mierop (52) in association with type B interrupted aortic arch. It was subsequently found in patients with tetralogy of Fallot, with or without pulmonary atresia, and has only been seen in patients with 22q11 deletion (25). This is an abnormality whose clinical significance appears to be that it is a marker for CATCH 22. Normally, the right innominate artery bifurcates into a common carotid and subclavian artery near its origin from the aorta (see Fig. 33.2A). However, in this anomaly, the innominate trifurcates in the neck, giving rise to external and internal carotids and the subclavian artery, which then travels caudally back to the thorax before heading out to the arm (Fig. 33.1).

Embryology

The presumptive embryology has been elegantly described by Kutsche and Van Mierop (52). This together with the observation of Rauch et al. (25) that abnormalities of subclavian artery origin are frequently associated with 22q11 deletion sheds light on an important pathway in the pathogenesis of arch anomalies in CATCH 22 patients. There appears to be a predilection for unilateral or bilateral absence or atresia of the embryonic fourth arch. When this occurs on the side opposite the definitive arch, there are three main variations in the fate of the subclavian artery: (a) origin from the descending aorta, that is, from the dorsal aorta distal to the seventh intersegmental artery—retroesophageal subclavian artery or circumflex aortic arch as described above (b) origin from the sixth arch—isolated subclavian artery, also described above, and (c) origin from the third arch, which, being more cephalad than

the fourth, gives origin to the subclavian artery in the neck rather than in the thorax.

When the fourth arch is absent or atretic ipsilateral to the definitive aortic arch, there are also three possibilities, which are elaborated upon below: (a) interrupted aortic arch, in which the sixth arch replaces the fourth, (b) persistent fifth aortic arch with atresia of the distal fourth, and (c) cervical aortic arch, in which the third arch replaces the fourth, analogous to cervical origin of the subclavian artery on the side opposite the arch. Of note is the fact that all of these have been seen in association with 22q11 deletion, and collectively are more common than cases with normal origin of the subclavian arteries and well developed fourth arches (22,24).

RIGHT AORTIC ARCH

Right aortic arches have in common (by definition) a single aortic arch that crosses over the right mainstem bronchus, passing to the right of the trachea. There are four major types of right arch: (a) with mirror-image branching and right descending aorta, (b) with retroesophageal left subclavian artery, (c) with retroesophageal diverticulum of Kommerell, and (d) with left descending aorta. There are also several infrequently occurring variations.

The incidence of right aortic arch among patients with tetralogy of Fallot has been reported to be anywhere from 13% to 34% (53); however studies vary as to the source of the material (chest roentgenogram, angiography, surgery, or postmortem examination) and frequently do not distinguish between specific types of right arch. The incidence in truncus arteriosus is generally higher than in tetralogy. An overall incidence of 8% in patients with D-transposition of the great arteries, compared to 16% in those with transposition, VSD, and pulmonary stenosis has been reported (54).

A relatively rare but important subset of right aortic arch is that with coarctation of the aorta. Pooling the results of two large series, one from our institution (55) and one from Shanghai Children's Medical Center (56), coarctation in right aortic arch represented only 1.7% of all coarctations and 2.9% of right aortic arches. Of interest is the high incidence of aberrant left subclavian artery—65% compared with only 25% of all right arches (16), and the similarly high incidence of vascular rings—70%. Most of these were long-segment coarctations.

Right Aortic Arch with Mirror-Image Branching

Mirror-image right arch has the first branch as a *left* innominate artery which, in turn, divides into left carotid and left subclavian arteries, the second as the right carotid, and the third as a right subclavian (Fig. 33.1). This is the left–right mirror of a normal left aortic arch. However, frequently that is the end of the symmetry, since the ductus arteriosus (or ligamentum arteriosum) is usually the left-sided one, arising from the base of the innominate artery rather than from the aortic arch. Therefore, typical mirror-image right aortic arch with left ductus or ligamentum *does not form a vascular ring*. This arch anomaly is almost always associated with congenital intracardiac disease. The most common association is with tetralogy of Fallot (48% in a series of 74 postmortem cases [57]), but truncus arteriosus communis, other conotruncal anomalies including transposition of the great arteries, double-outlet right ventricle, right ventricular aorta with pulmonary atresia, and anatomically corrected malposition were also seen. In addition, lesions not usually considered conotruncal anomalies such as pulmonary atresia with intact ventricular septum, conoventricular VSD

with anomalous muscle bundle of the right ventricle, and isolated VSD are occasionally found to have mirror-image right arch.

A rare variation of mirror-image right aortic arch has a left ductus or ligamentum arising from a retroesophageal dimple pointing toward the left from the right-sided descending aorta. This does form a vascular ring (Fig. 33.1). This is different from right arch with diverticulum of Kommerell in that no arch vessel arises from the dimple. Unlike other patients with mirror-image right aortic arch, the few reported cases with retroesophageal ductus dimple appear not to have associated congenital heart disease (58). Because of the directly AP arrangement of the ascending and descending aorta in right arches, the right mainstem bronchus is subject to compression between the RPA and the descending aorta. In one case, this compression was exaggerated by a unique ligamentum arteriosum passing beneath the right bronchus in a patient with discontinuous branch pulmonary arteries with a thrombosed left pulmonary artery arising exclusively from a left ductus off the left innominate artery (59). Watanabe et al. (60) demonstrated that a right aortic arch with L-transposed or malposed aorta can cause tracheal compression because of elongation of the aortic arch.

Embryology

The presumptive pattern of mirror-image right arch development includes dissolution of the left dorsal aorta distal to the origin of the seventh intersegmental artery (distal subclavian artery precursor) so that the left fourth arch becomes the proximal subclavian artery rather than remaining as an aortic arch (Fig. 33.7). Typically, the right sixth (ductal) arch involutes

while the left sixth persists. However, with disappearance of the left dorsal aorta distal to the left seventh intersegmental artery, the sixth arch usually connects to the proximal or subclavian artery side of the disruption. Thus, in the definitive arch the left ductus arises from the underside of the left innominate artery and passes to the left pulmonary artery appearing as a congenital modified left Blalock-Thomas-Taussig shunt. Alternatively, the left sixth arch will disappear and the right persist giving a true mirror image of normal, that is, a ductus connecting the underside of the right-sided arch with the RPA. Other cases, particularly when associated with tetralogy of Fallot, may have dissolution of both ductus. Finally, in those with retroesophageal ductus dimple the left sixth arch connects left pulmonary artery with the distal left dorsal aorta (Fig. 33.8).

Diagnosis and Management

Since this type of right arch usually produces no retroesophageal compression or vascular ring, there are, with rare exceptions, no symptoms produced by the arch itself. Therefore, the diagnosis is usually made during imaging of the associated congenital intracardiac disease. The distinctive branching pattern can be used for echocardiographic and angiographic diagnosis, while the appearance of a right-sided indentation of trachea and esophagus on plain radiograph and barium esophagography, respectively, but without posterior impression on the esophagram, permits the diagnosis to be made with those modalities. The presence of a left innominate artery in a patient with symptoms suggestive of a vascular ring and in the absence of cyanotic congenital heart disease should suggest the differential diagnosis of the rare right arch, retroesophageal ductus or the more common right arch, or left descending aorta or double aortic arch with atretic left arch distal to the subclavian artery (discussed below) (differentiated by presence of a left upper descending aorta).

No treatment of right aortic arch per se is required; however, it may be helpful for surgeons to know the sidedness of the aortic arch in certain circumstances. For systemic-to-pulmonary shunts, the classical Blalock-Thomas-Taussig (subclavian artery to pulmonary artery, direct end-to-side) anastomosis or the modified form (polytetrafluoroethylene [Gore-Tex] tube graft interposition side-to-side anastomosis of subclavian artery to pulmonary artery) is best carried out using the side with an innominate artery. With the classical form, the more nearly horizontal takeoff of the subclavian artery makes kinking of the vessel less likely when the cut end is brought down to the level of the pulmonary artery than with the subclavian artery arising directly from the arch. Even with Gore-Tex tube graft interposition, the innominate is a more favorable site of origin since the overall diameter of the innominate is greater, making the proximal anastomosis easier. Furthermore, the angle of takeoff is less acute, making kinking of the vessel of origin less likely even if there is some downward traction after completion of the anastomosis. Another situation in which knowledge of the side of the aortic arch may be useful is in the repair of esophageal atresia and tracheoesophageal fistula where it may be desirable to avoid having the arch obscure the view of the fistula (Fig. 33.9).

Figure 33.7. Cervical origin of the right subclavian artery. Slightly right anterior oblique view of 3-D shaded surface display from MRI. Note the high (i.e., cervical) origin of the RSCA from the right innominate artery (R Innom a) and the downward course into the thorax. Compare with Figure 22.2A. Dotted line shows expected location of absent embryonic fourth arch (IV). Note superior location of embryonic third arch (III) component of RSCA. L innom v, left innominate vein.

Right Aortic Arch with Retroesophageal Left Subclavian Artery

Right aortic arch with retroesophageal left subclavian artery (the nonvascular-ring form of anomalous or aberrant subclavian) consists of an arch passing to the right of the trachea with the following sequence of brachiocephalic arteries: left carotid, right carotid, right subclavian, and retroesophageal

Figure 33.8. Right aortic arch, mirror-image type. **A:** Anterior view of 3-D shaded surface display from MRI. Sequence of arch vessels is L Innom a, RCA, RSCA. **B:** Left posterior oblique view. Note incidental retroaortic L Innom v. There was no ductus arteriosus in this case. **C:** Embryonic arch diagram showing dissolution of left dorsal aorta after proximal migration of left subclavian artery. Note that left fourth arch forms proximal left subclavian artery and left sixth (ductal) arch (if present) extends from underside of left innominate artery to left pulmonary artery.

left subclavian arteries (Fig. 33.1). This differs from the arch anomaly described below in that the proximal left subclavian artery is not significantly larger in caliber than its more distal portion (i.e., no aortic diverticulum). Therefore, there is no left-sided ductus arteriosus or ligamentum arteriosum and thus no vascular ring. Many of these patients have associated conotruncal anomalies. As has been noted previously, aberrant subclavian artery has a higher incidence of 22q11 deletion than does mirror-image right aortic arch (22).

Embryology

This is similar to the right arch with retroesophageal diverticulum with involution of the left fourth aortic arch, but with loss of the left sixth (ductal) arch as well (Fig. 33.10C). In this way, the left dorsal aorta becomes *only* the proximal left subclavian artery and not the “beginning” of the descending aorta.

A right sixth arch, if present, connects RPA with right dorsal aorta, which is part of the definitive right arch.

Diagnosis and Management

The diagnosis may be suspected from barium esophagography with a relatively small posterior indentation on the esophagus passing upward to the left. Since there is no vascular ring, the trachea is unaffected except for the slight leftward deviation seen with virtually all right aortic arches. As noted above, echocardiography may be expected to identify the first branch of the aorta as a left carotid artery (since it does not bifurcate proximally like an innominate artery and is similar in caliber to the second branch—right carotid artery), but appreciation of the size of the retroesophageal vessel itself may be difficult. Both MRI and angiography can demonstrate the size of the left subclavian artery that distinguishes this lesion from right

Figure 33.9. Right aortic arch with retroesophageal left ligamentum arteriosum. Shaded surface display from gadolinium-enhanced 3-D MRI dataset. **A:** Posterior view showing mirror-image branching pattern—first arch vessel being left innominate artery (L Innom a) giving rise to left subclavian (LSCA) and carotid (LCA) arteries, second is right carotid (RCA), then right subclavian (RSCA)—of right aortic arch (RAoA) but with ductus dimple (DD) pointing toward the left. **B:** Left posterior oblique view showing no posterior tethering of the left innominate artery indicating that this is not a double aortic arch with atretic left arch (compare with Fig. 33.18A). Left carotid and subclavian arteries superimposed in this view. Left innominate vein (L Innom v) is seen anterior to L Innom a. **C:** Overhead view showing the right aortic arch (RAoA) and right descending aorta (DAo) with the DD pointing toward the left, indicating a vascular ring. **D:** Embryonic arch diagram shows mirror-image right arch branching pattern with LPA connected by left sixth arch (ligamentum) to dimple formed by remnant of left dorsal aorta.

aortic arch with retroesophageal diverticulum. Since there is no vascular ring, there is usually no need for treatment other than that of associated anomalies.

Right Aortic Arch with Retroesophageal Diverticulum of Kommerell

Right arch with diverticulum of Kommerell is the second most common vascular ring after double aortic arch. It is far more

common than its mirror image described above. It has as its first branch the left carotid artery, second the right carotid artery, third the right subclavian artery, and finally a retroesophageal vessel from which the left subclavian artery arises and the left ductus arteriosus or ligamentum arteriosum connects (Fig. 33.1). This combination of vessels produces a vascular ring. The true incidence of this lesion is more difficult to obtain than that of mirror-image right arch where virtually all patients have associated intracardiac disease. However, of 26 consecutive patients undergoing surgical division of vascular rings at

Figure 33.10. Right aortic arch with retroesophageal left subclavian artery. A: Slightly left anterior oblique view and (B) posterior view of 3-D shaded surface display from MRI. Note the constant caliber of the left subclavian artery emerging from the aorta behind the trachea, compared with the marked tapering of a diverticulum of Kommerell (Fig. 33.11B). Note incidental finding of left subclavian vein (LSCV) leading to retroaortic innominate vein (not labeled). C: Embryonic arch diagram showing dissolution of left fourth and sixth arches. In the absence of a left ductus, the retroesophageal left dorsal aorta does not form a diverticulum, and there is no vascular ring.

our institution, five (19%) had right arch, retroesophageal diverticulum, and most of them had no other heart defect. What is more, many people with this arch anomaly are asymptomatic and therefore go unrecognized except for incidental discovery.

If the ductus arteriosus is patent, it is easy to understand how one might visualize the complete ring formed by the aortic arch on the right, retroesophageal vessel supplying the left subclavian posteriorly, the ductus on the left, and the pulmonary artery anteriorly. However, if the ductus is closed, it is not intuitive that one could distinguish this from the more benign right arch with retroesophageal subclavian artery (non-ring) discussed above. The difference is the diverticulum of

Kommerell, which is a much larger vessel than the subclavian artery itself. Typically, the origin of the diverticulum is equal in diameter to the descending aorta and tapers to the subclavian artery caliber at the site of juncture with the left ligamentum after passing behind the trachea and esophagus.

Congenital absence of the left carotid artery is a rare association with right arch, diverticulum of Kommerell (61). Its importance lies in the fact that it is one of three exceptions to the general rule that the first arch vessel contains a carotid artery *opposite* to the side of the arch. Furthermore, if resection of the diverticulum is contemplated, the subclavian must be connected to the ascending aorta or to the right carotid.

Figure 33.11. Right aortic arch, retroesophageal diverticulum of Kommerell. **A:** Left anterior oblique view of 3-D shaded surface display from MRI. Trachea (green) and esophagus (E) are compressed by diverticulum (Div) tethered by ligamentum arteriosum (not visualized) to pulmonary artery (blue). **B:** Posterior view shows tapered Div behind esophagus giving rise to LSCA. The tracheal deviation to the left is seen through the translucent D Ao. Compare with Figure 33.9A. **C:** Cranial view shows trachea (green) and esophagus (E) compressed between Div and LCA and pulmonary artery (blue). **D:** Embryonic arch diagram showing dissolution of left fourth arch and formation of retroesophageal diverticulum from left dorsal aorta in the presence of a left sixth arch—left ligamentum (L Lig [IV]).

Embryology

Disappearance of the left fourth embryonic arch with persistence of the left sixth (ductal) arch between the truncal aortic sac (pulmonary artery precursor) and left dorsal aorta accounts for the findings in this arch anomaly (Fig. 33.11D). Note that the left dorsal aorta is not merely the proximal left subclavian artery but is also the continuation of the left sixth aortic arch leading to the fused dorsal aortae. Since the normal fetal ductus carries nearly the entire output of the right ventricle, the left dorsal aorta would also carry that amount and would become significantly larger than the subclavian artery. This size discrepancy persists after ductal closure, giving the diverticulum its characteristic appearance. In the rare variant with absence of the left carotid, there is absence of both the

left fourth embryonic arch and the truncal aortic sac connection to the left third.

Diagnosis and Management

The presentation in symptomatic patients is usually that of a vascular ring. With that history, the appearance of a right aortic arch on a plain chest roentgenogram should raise the question of this anomaly and prompt further, more specific evaluation. Barium esophagram reveals a large posterior indentation on the esophagus similar to that seen in Figure 33.11E, F (in contrast to the smaller defect seen with simple retroesophageal subclavian artery [Fig. 33.3E]). However, rare vascular rings such as left aortic arch with right descending aorta and right ligamentum can give similar findings on barium study, and since the

surgical approach is different, this form of imaging should not be considered definitive. While the ligamentum arteriosum is not visualized with any of the current imaging modalities, its presence is guaranteed by the characteristic appearance of the abruptly tapered diverticulum. Echocardiography will show the left carotid artery arising alone as the first arch vessel, but definitive diagnosis requires that the diverticulum be followed out to the point at which the caliber changes to that of the smaller subclavian artery. This is usually not possible since the trachea itself and nearby lung may thwart attempts to see this area. Angiography demonstrates the characteristic branching pattern but more importantly shows the abrupt change in caliber from diverticulum to subclavian artery. As mentioned previously under left aortic arch with retroesophageal right subclavian artery, angiography in the straight AP view may produce superimposition of the posterior subclavian artery on the more anterior left carotid giving the appearance of a left innominate artery as in mirror-image right aortic arch and therefore not a ring. However, careful single-frame viewing of cineangiography will confirm the separate origins. Contrast injection in the more distal portion of the arch will better delineate the plump aortic diverticulum giving rise to the noticeably smaller subclavian artery. Angiography while definitive, showing both the characteristic branching pattern and the typical appearance of the aortic diverticulum requires arterial catheterization, less desirable in the young infant. MRI is ideal for making this diagnosis, being noninvasive and having the ability to display both vascular and airway structures. Axial or transverse imaging demonstrates the aortic arch to the right of the trachea and the diverticulum posterior to it. Coronal imaging shows the V-shaped juncture of the aortic diverticulum and the more right-sided descending aorta. However, computer-generated shaded surface displays (3-D representations) permit viewing of the entire aortic arch at once and in relationship to trachea and pulmonary artery (Fig. 33.11A–C) and give the surgeon a clear anatomical image with which to proceed.

The majority of people with this arch anomaly are asymptomatic. Treatment is surgical division of the ductus or ligamentum in those patients who are symptomatic. This is usually performed through a left thoracotomy. Video-assisted thoracoscopic surgery, or VATS, has been shown to be effective and comparable in procedure time and length of stay to open thoracotomy (62). Some surgeons prefer a median sternotomy approach, particularly if an intracardiac defect will also be addressed in the same operation. Some surgeons advocate not only division of the ligamentum but also resection of the diverticulum and transfer of the left subclavian artery to the left carotid artery because of the recurrence of symptoms in some patients due to compression from an aneurysmal diverticulum and traction by the subclavian artery (63). In adult cases where the diverticulum has become aneurysmal, there is a significant risk of dissection or rupture (64,65); the usual treatment is resection. A novel hybrid approach in which both subclavian arteries are connected by grafts to their respective carotid arteries by minimally invasive surgery followed by covered stent placement in the aortic arch to exclude the aneurysmal diverticulum has also been employed (66).

In those patients undergoing surgery for another lesion such as an intracardiac abnormality or repair of tracheoesophageal fistula, even an “asymptomatic” ligamentum should be divided. With esophageal atresia, a symptomatic ring may be avoided when repairing the esophagus outside the ring.

Right Aortic Arch with Left Descending Aorta and Left Ductus (Ligamentum) Arteriosus(um)

Right arch, left descending aorta, also known as right aortic arch with retroesophageal segment or circumflex right aortic

arch, is similar in presentation to right arch with retroesophageal diverticulum (above), but it is less common. Unlike cases with retroesophageal diverticulum in which the aorta after passing over the right mainstem bronchus descends for some distance on the right, then gradually crosses to the left before reaching the level of the diaphragm, right arch left descending (aorta) has the aortic arch itself cross the midline to the left at the level of the T4 or T5 vertebral body at which point it gives rise to the left ductus (ligamentum) arteriosus(um). Another difference is that some of these cases have a mirror-image branching pattern—left innominate, right carotid, right subclavian (Fig. 33.1)—and can therefore be erroneously misdiagnosed as a nonring, while others have left carotid, right carotid, right subclavian, and finally the left subclavian (Fig. 33.1). Yet another pattern has an aberrant left innominate artery—right carotid, right subclavian, left innominate as the last vessel (67), sometimes with coarctation of the right arch (68). However, in all of these it is the aortic arch that is retroesophageal, not the subclavian artery, innominate artery, or an aortic diverticulum.

Embryology

Two forms exist with dissolution of either the left dorsal aorta distal to the takeoff of the left subclavian artery (Fig. 33.12G) or the left fourth arch (Fig. 33.13E). The distal portion of the definitive arch is comprised of the retroesophageal right-sided dorsal aorta. The persistent left sixth arch connects to the left-sided dorsal aorta completing a vascular ring.

Diagnosis and Management

The findings on chest roentgenogram and barium esophagography (Fig. 33.12E) may be similar to those findings in right arch with retroesophageal diverticulum. Differences include a downward to the left instead of upward to the left orientation of the esophageal indentation (Fig. 33.12F). Furthermore, in some cases the descending aorta itself can be seen on the left of the spine instead of the right, but this is not a consistent finding. When associated with a hypoplastic arch (69), this anomaly can be mistaken for interrupted aortic arch (70).

With a projection image such as angiography it may not be clear whether the aorta passes anterior to the trachea as it courses from right ascending to left descending, as is seen with a normal left aortic arch, or posterior to the trachea, that is, a right aortic arch with left descending. A clue to which is the case (without attempting steep cranial angulation—usually more confusing than helpful because of overlapping shoulder, head, liver) is the order of brachiocephalic artery branching. In the case of right aortic arch with left descending aorta the first vessel contains the left carotid artery, whereas in normal left arches, a vessel containing a right carotid is first. MRI can avoid some of the pitfalls seen with projection images and can delineate the entire aorta, not only in its normal rightward ascending and leftward descending segments, but definitively in its relationship to the trachea (Fig. 33.12A,B).

Division of the vascular ring is indicated when patients are symptomatic, although these are typically loose rings. However, an adult with dysphagia may require more than simple division of the ligamentum. Actual division of the aortic arch with mobilization of the retroesophageal portion and reanastomosis of ascending and descending aorta using a tube graft may be necessary to relieve the esophageal compression (71,72). Alternatively, resection of the retroesophageal portion, advancement of the aortic arch, and direct end-to-side anastomosis of the descending aorta to the ascending to the left of the trachea has also been used (73,74).

Figure 33.12. Right aortic arch, left descending aorta, left innominate artery. **A:** Cranial view of 3-D shaded surface display from MRI showing takeoff of brachiocephalic arteries: left innominate artery giving rise to LCA and LSCA, RCA, and RSCA. **B:** Same view as (A) but with trachea (green), esophagus (blue), and pulmonary artery (red) showing further crowding. Anterior (C) and posterior (D) of same reconstruction showing retroesophageal course of circumflex aortic arch with sharp turn inferiorly at point of attachment of ligamentum arteriosum (arrow) to descending aorta. Barium esophagram in lateral view (E) showing large posterior indentation, and AP view (F) showing bilateral indentations on the esophagus. Similar patterns are seen with double arch and right arch with diverticulum. **G:** Embryonic arch pattern similar to Figure 33.9D above but with left descending aorta instead of right.

Figure 33.13. Right aortic arch with left descending aorta and aberrant left subclavian artery. 3-D shaded surface displays from MRI. **A:** Anterior view showing right-sided AAo and left-sided descending aorta (labeled in C and D). First arch vessel is left carotid artery; last vessel is left subclavian artery. Patent ductus arteriosus (PDA) connects MPA to descending aorta. **B:** Left lateral view. **C:** Posterior view showing marked angulation between circumflex aortic arch (Circ Ao) and DAo. **D:** Overhead view shows complete ring of vessels surrounding space occupied by trachea and esophagus (not displayed). **E:** Embryonic arch diagram showing left-sided descending aorta and dissolution of left fourth arch with persistence of left sixth arch—ligamentum (L Lig [VI]). Compare with Figure 33.11D.

Right Aortic Arch with Retroesophageal Innominate Artery

Right aortic arch with retroesophageal innominate artery is another rare abnormality of the aortic arch system. Contrary to the general rule that the first arch vessel contains a carotid artery contralateral to the aortic arch, in these cases the sequence of brachiocephalic vessels is right carotid, right

subclavian, retroesophageal left innominate artery (Fig. 33.1). The ductus (or ligamentum) arteriosus(um) completes a vascular ring as it connects the left pulmonary artery with the base of the so-called innominate artery.

Embryology

The apparent site of arch dissolution is between the left branch of the trunco-aortic sac and the third arch (Fig. 33.14D) with

Figure 33.14. Right aortic arch with retroesophageal left innominate artery (L Innom). Shaded surface display from gadolinium-enhanced 3-D MRI dataset. **A:** Anterior view showing ascending aorta (Ao) superimposed on right aortic arch giving rise to right carotid (RCA) and right subclavian (RSCA) arteries. There is a retroesophageal diverticulum that acts as a left innominate artery (L Innom a) giving rise to left carotid (LCA) and left subclavian (LSCA) arteries. The very large caliber diverticulum is connected to the pulmonary artery (PA) by way of a left ligamentum arteriosum (Lig), which is not visualized. Dao, descending aorta. **B:** Posterior view showing same arch vessels as in (A). RPA forms anterior portion of vascular ring. Open arrow indicates left pulmonary artery end of ligamentum connecting pointed portion of left innominate artery (L Innom). **C:** Cranially angulated view showing vascular ring formed by right aortic arch (RAoA) on the right, left innominate artery (L Innom a) posteriorly, left ligamentum arteriosum (Lig) to the left, and pulmonary artery (PA) anteriorly. The location of the trachea and esophagus is indicated by asterisk. Ao, ascending aorta. **D:** Diagram of embryonic arch contributions. Dissolution of left limb of trunco-aortic sac (L TA Sac) connection to third arch (III); persistence of left third arch (instead of fourth arch) connection to left dorsal aorta. R TA Sac, right limb of trunco-aortic sac.

absence of the fourth arch. Thus the definitive aortic arch is formed by the right branch leading to the right fourth arch, which, in turn, connects to the right dorsal aorta. The left dorsal aorta supplies the left seventh intersegmental artery (distal left subclavian) and the distal connection to the left third arch (common carotid artery).

Diagnosis and Management

With so few cases in the literature (75), it is difficult to draw conclusions about presentation and management. Tracheal compression seems to be the rule, though the degree of symptomatology varies considerably. The important anatomical clues to the diagnosis by any imaging modality are the presence of a single carotid artery arising from the proximal aorta. The other anomalies with that finding are also rare: interrupted aortic arch with interruption between the two carotid arteries and isolated left carotid or innominate artery, as well as congenital absence of the carotid artery contralateral to the side of the arch (see below). The differentiating feature is the presence of a normal-sized (right) aortic arch—missing in arch interruption—and the distal origin of the carotid artery from that arch—not present with isolated carotid or innominate or in congenital absence of the contralateral carotid. If symptomatic from the vascular ring, division of the ductus or ligamentum is in order. Conceivably in the adult, detachment of the innominate artery from the distal arch and reimplantation in the ascending aorta might be necessary based on similar arch anomalies mentioned above in which the retroesophageal vessel continued to cause dysphagia even after relief of the ring by division of the ligamentum.

Right Aortic Arch with Isolation of Contralateral Arch Vessel

Isolation of brachiocephalic vessels is relatively uncommon. The term isolation means that the particular vessel arises exclusively from the pulmonary artery via the ductus arteriosus (or ligamentum) but without connection to the aorta. Three different forms have been noted: isolation of the left subclavian

artery (Fig. 33.1), isolation of the left carotid, and isolation of the left innominate artery. Isolated left subclavian is by far the most common of the three. Luetmer and Miller (76) reviewed the literature to 1990 describing 39 cases demonstrated by angiography or at postmortem examination. Congenital heart disease was found in more than half the cases with two-thirds of those having tetralogy of Fallot. There are sporadic reports of isolated left innominate artery (77). A very rare example associated with single left ventricle with L-loop ventricular arrangement and aortic atresia is shown in Figure 33.1. A forme fruste is shown in Figure 33.16A with a small innominate artery and larger subclavian and carotid, suggesting that during fetal life they had been fed by a left ductus that had since closed. A unique case of isolated subclavian artery in a patient with tetralogy of Fallot had a collateral vessel from the abdominal aorta fill the subclavian in addition to the usual retrograde flow from the vertebral artery (78).

Embryology

All cases of isolated arch vessels derive from two ipsilateral breaks in the aortic arch system (Fig. 33.15B). In isolated subclavian artery, the distal left dorsal aorta involutes after cephalad migration of the left seventh intersegmental (subclavian) artery to the level where left sixth (ductal) arch normally joins the proximal dorsal aorta. This together with involution of the left fourth arch leaves the subclavian isolated from the aortic arch but connected to the pulmonary artery via the ductus. In similar fashion one could imagine the disappearance of the left fourth arch and the left branch of the aortic sac with the sixth arch connecting the pulmonary artery portion of the trunco-aortic sac to the third arch (common carotid artery precursor). With disruption of the left fourth arch, the left seventh intersegmental artery remains connected to the descending aorta via the left dorsal aorta producing a retroesophageal left subclavian artery. It is postulated that isolated innominate artery (see Figs. 33.15B and 33.16D) derives from dissolution of the left branch of the trunco-aortic sac connection to the third arch, loss of the fourth arch, and dissolution of the connection of distal left dorsal aorta with the left sixth (ductal)

Figure 33.15. Right aortic arch with isolation of left subclavian artery. **A:** Anterior view of 3-D shaded surface display from MRI shows exclusive origin of LSCA from left PDA. Sequence of arch vessels arising from aorta is LCA, RCA, and RSCA. **B:** Embryonic arch diagram showing ipsilateral loss of left fourth arch and dorsal aorta with persistence of ipsilateral sixth arch.

Figure 33.16. Isolated left innominate artery. **A:** *Forme fruste*. Anterior view of 3-D shaded surface display from MRI. Note small left innominate artery (L Innom a) giving rise to larger caliber LSCA and LCA. These latter two appear to arise from a point consistent with a ligamentum arteriosum (*open arrow*) and apparently received more flow from that vessel than from the aorta during fetal development. **B:** Embryonic arch diagram showing hypoplasia of left limb of truncus aortic sac and left fourth arch with dissolution of connections to left Dors Ao and persistence of left sixth arch. **C:** Completely isolated left innominate artery (L Innom). Slightly left anterior oblique and slightly cranially angulated view of shaded surface display from CT scan of infant with single left ventricle and diminutive right ventricular outflow chamber with L-transposition of the great arteries and aortic atresia. The L Innom is fed by the left patent ductus arteriosus (PDA[L]) and possibly retrograde from circle of Willis via left vertebral and carotid arteries. There is a right aortic arch (RAoA) and markedly hypoplastic ascending aorta (AAo) fed exclusively from the main pulmonary artery (MPA) via the right patent ductus (PDA[R]). Branch pulmonary arteries shown in *blue*, trachea in *green*, ascending aorta and coronary arteries in *red*. **D:** Embryonic arch diagram showing dissolution of left limb of truncus aortic sac and left fourth arch with dissolution of connections to left Dors Ao and persistence of left sixth arch supplying left carotid (distal third arch) and left subclavian (left seventh intersegmental artery).

arch. Thus the pulmonary portion of the truncus aortic sac feeds the left seventh intersegmental (subclavian) artery via the sixth and the carotid artery in turn via the distal left third arch similar to retroesophageal innominate artery described above. The resulting confluence of carotid and subclavian arteries is

analogous to an innominate artery. An alternative mechanism based on identification of a pulmonary-to-brachiocephalic artery connection proximal to or upstream from the ductus in chick embryos is explained by an abnormal partition of the truncus aortic sac (79).

Diagnosis and Management

Cases of isolated brachiocephalic arteries may have diminished pulses or lower blood pressure in the affected artery. When the subclavian and vertebral arteries are involved, the possibility of subclavian steal syndrome exists in which blood flows down the vertebral artery into the subclavian, particularly when the arm is exercised. In 13% of cases reviewed by Luetmer and Miller (76), this produced cerebral insufficiency. Another 13% showed signs of left arm ischemia. If the ductus remains patent, pulmonary artery steal can occur with flow down the vertebral artery through the ductus into the low-resistance pulmonary artery (80). One case of underdevelopment of the left arm with isolated subclavian artery showed catch-up growth after reimplantation in the left carotid. Another case with left hemisphere atrophy associated with global developmental delay and bulbar dysfunction in the face of isolated left innominate artery with a patent ductus and retrograde left carotid flow was found (77). The diagnosis should be suspected in any patient with right aortic arch and diminished pulse amplitude or blood pressure in the left arm, although coarctation of a right arch with aberrant left subclavian artery could also produce these findings. Contrast injection in the aortic arch shows delayed filling of the subclavian artery via the vertebral and various collateral arteries (81). Barium esophagography is not helpful in making this diagnosis other than demonstration of the right aortic arch. Doppler echocardiography may be able to demonstrate the reversal of flow in the vertebral artery that would corroborate this diagnosis, but phase-encoded velocity mapping on MRI can also be definitive.

Surgical management in children consists of repair of the accompanying heart disease and ligation of the ductus, if patent, to prevent pulmonary steal. Patients with central nervous system symptoms or claudication of the left arm should have surgical reimplantation of the subclavian artery into the carotid or aorta. Some have advocated this approach in asymptomatic cases to avoid subclavian steal later in life (82).

CERVICAL AORTIC ARCH

Cervical aortic arch is a rare anomaly in which the arch is found above the level of the clavicle (as high as the C2 vertebral body). There are two main subcategories of cervical arch: those with anomalous subclavian artery and vascular ring, with either descending aorta contralateral to the arch (see Fig. 33.5) or retroesophageal diverticulum and those with a virtual normal branching pattern. The first and larger group usually has a right aortic arch. This group is further subdivided into those with separate origins of the internal and external carotid arteries from the arch and those with a common carotid artery or a bicarotid trunk in which both common carotid arteries arise from a single vessel and the subclavian arteries both arise separately from the distal arch (83). Separate origin of the vertebral artery from the arch can be seen in each of the groups. While most of the patients with contralateral descending aorta have an anatomical vascular ring from the aortic arch on the right, retroesophageal segment of aorta posteriorly, ligamentum arteriosum to the left, and pulmonary artery anteriorly, only about half are symptomatic from the ring. When a bicarotid trunk accompanies the contralateral descending aorta form of cervical arch, tracheal or esophageal compression between the "V" of the bicarotid trunk and the retroesophageal aorta may occur without a complete vascular ring.

The second group (with ipsilateral descending aorta—nonring) typically has a left aortic arch. Aortic arch obstruction due to a long, tortuous, hypoplastic retroesophageal segment is an uncommon but well-documented association (84). More discrete

coarctations have been reported in both the ring and nonring groups (85). For reasons that are not clear, stenosis or atresia of the origin of the left subclavian artery is sometimes seen in either group (86).

Embryology

It would appear that the embryologic explanations for the various subgroups mentioned above are different. The normal common carotid artery comes about from the dissolution of the segment of dorsal aorta between the third and fourth embryonic arches, the so-called ductus caroticus. Both internal and external carotid arteries arise from the third arch. If the ductus caroticus were to persist while the embryonic fourth arch involutes, the embryonic third arch would become the definitive arch with separate internal and external carotid arteries arising from it (as they had when the third arch was, in part, the common carotid artery) (87). The third arch being one branchial pouch higher than the fourth arch would be expected to be more cephalad after completion of arch development. This type of cervical arch (i.e., with separate internal and external carotid arteries arising directly from the arch) due to persistent ductus caroticus and absent fourth arch has been described in chromosome 22q11 deletion as previously mentioned (88).

An alternative explanation for this subgroup and more plausible for the other groups that have normal common carotid arteries is a failure of the normal descent of the aortic arch system from its cephalic location at 3 weeks to its normal intrathoracic location by 7 weeks' gestation (89). The etiology of this failure of caudal migration is not known.

Diagnosis and Management

Cervical arches may present as pulsatile masses in the supraclavicular fossa or in the neck. In infants, prior to the appearance of a mass, the presenting signs may be those of a vascular ring, namely, stridor, dyspnea, or repeated lower respiratory infections. In the adult, the most likely symptom from a vascular ring is dysphagia. In those patients with stenosis or atresia of the left subclavian artery and origin of the ipsilateral vertebral artery distal to the obstruction, a subclavian steal may exist with central nervous system symptomatology. In the presence of a pulsatile neck mass, a presumptive diagnosis can be made by notation of loss of femoral pulses during brief compression of the mass (86).

The diagnosis of cervical arch may be suspected on plain chest roentgenogram by the presence of a widened upper mediastinum and the absence of the aortic knob. Evidence of anterior deviation of the trachea is in favor of the diagnosis. In the past, angiography has been the standard diagnostic imaging tool, and in those cases with intracardiac anomalies, probably remains so. However, in those without congenital heart disease, the diagnosis of cervical aortic arch can be made by echocardiography. Treatment is necessary if the cervical arch is complicated by arch hypoplasia, symptomatic vascular ring, or rarely aneurysm of the cervical arch itself (90). In these cases, the surgical approach is dictated by the specific complicating feature. In some cases with cervical right aortic arch and a tortuous, hypoplastic retroesophageal segment, repair is accomplished by left-sided ascending-to-descending aorta anastomosis or tube graft interposition (91). Separate origin of external and internal carotid arteries from the arch warrants screening for 22q11 deletion.

DOUBLE AORTIC ARCH

Double aortic arch, as the name implies, is an anomaly in which both right and left aortic arches are present. Several

variations on this basic theme occur: both arches of similar size (Fig. 33.1), hypoplasia of one arch (Fig. 33.16) (usually the left), and atresia of one arch (Fig. 33.1) (usually the left). In addition, a ductus arteriosus or ligamentum may be present. Typically, the right arch is the more superiorly located.

While all double aortic arches technically form complete vascular rings around the trachea and esophagus, the branching pattern evident from various imaging modalities is determined by the patency of the various arch components and the side of the descending aorta. For example, while a double arch with both arches patent will show relatively symmetrical origins of each of the four major brachiocephalic arteries from their respective arches (Fig. 33.17K,L), double arch with atretic left arch distal to the origin of the left subclavian artery (Fig. 33.18) will have a branching pattern similar to a mirror-image right aortic arch, that is, an apparent left innominate artery,

followed by a right carotid and right subclavian, but with a left descending aorta. In fact, this pattern in conjunction with signs of tracheal compression, may be indistinguishable (except at surgery) from the rare anomaly right aortic arch with left descending aorta, unless, as in Figure 33.18A, a distal left arch stump is present. Similarly, double arch with atretic left arch between left carotid and left subclavian can mimic right aortic arch with retroesophageal diverticulum of Kommerell. Atretic right arch is quite rare (92) but can simulate left arch variants. Of 17 patients at one institution undergoing division of the vascular ring, 11 had a left descending aorta, six, a right (93). A review of 26 patients undergoing surgical division of vascular rings over an 8-year period at The Children's Hospital of Philadelphia showed 20 to have double aortic arches. Seventeen had both arches patent with the right arch larger in 16. The other three patients had an atretic left arch.

Figure 33-17 Double aortic arch, both patent. A–D: Spin echo MRI (coronal cuts, anterior to posterior) showing ascending aorta (A Ao) dividing into equal-sized right (R) and left (L) aortic arches reuniting posteriorly as the descending aorta. Coronal images of patients having double arch with (E) dominant right and (F) rare case of dominant left.

Figure 33-17 (Continued) G–J: transverse cuts, cranial to caudal, from same patient as (A–D). Note marked decrease in caliber of trachea (T) from (G–H), indicative of tracheal compression. K: Left posterior oblique with cranial angulation view of 3-D shaded surface display from MRI in same patient as (A–D) and (G–J). Note double aortic arch with nearly equal-sized right (R arch) and left (L arch) distal aortic arch components. L: Similar view of patient with rare dominant left arch.

Double aortic arch is rarely associated with congenital heart disease, but when present, tetralogy of Fallot is most common (94), with transposition of the great arteries a distant second (94,95), and a single reported case of congenitally corrected transposition (96). Infrequent associated arch abnormalities including coarctation of the left (97) or both arches (98) and cervical left aortic arch (99) have been noted.

Embryology

Double aortic arch represents a persistence of both right and left embryonic fourth branchial arches joining the aortic portion of the trunco-aortic sac to their respective dorsal aortae, both of which persist as well. Thus double aortic arch with both arches patent appears as persistence of the entire hypothetical double arch (Fig. 33.1) though usually with only one sixth (ductal) arch, whereas double arch with atretic left arch has patterns similar to either right arch with retroesophageal diverticulum or right arch, left descending aorta (compare Fig. 33.18B with Fig. 33.13E or Fig. 33.18C with Fig. 33.12G).

In keeping with the theme of absent or atretic fourth arches in 22q11 deletions, double arch with atretic left arch is more commonly associated with those syndromes than double arch with both widely patent.

Diagnosis and Management

The clinical manifestations of double aortic arches, as with the other vascular rings, are related to the tightness of the ring. With both arches widely patent, the rings are typically tight, and patients present with stridor in the first weeks of life, whereas with double arch and atretic left arch, the rings are usually looser, with presentations at 3 to 6 months of age or later. Rarely, double aortic arches present in adulthood with swallowing or respiratory symptoms (100). Even rarer is the case of an 85-year-old woman with an asymptomatic double aortic arch—both patent—who presented with back pain from an aortic dissection of an aneurysmal left arch (101). At the other extreme of age is a 22-week fetus with echocardiographic findings of congenital high airway obstruction

Figure 33.18. Double aortic arch with atretic left arch. A: Left lateral view of 3-D shaded surface display from MRI with atretic left arch distal to left subclavian artery (LSCA) as in (C) (below). Patent proximal left aortic arch (Prox L Arch) connects LSCA with left carotid artery (LCA). Presence of a distal left arch (Dist L Arch) aimed at Prox L Arch and not at pulmonary artery (blue) assures atretic left arch. B: Diagram of embryonic arches showing vascular ring formed by atretic left fourth arch (IV [atr]). C: Diagram of embryonic arches corresponding to 3-D surface display in A (above) showing atretic distal portion of dorsal aorta (Dors Ao [atr]).

syndrome with fetal ascites and enlarged echogenic lungs subsequently found by fetal echocardiography to be due to a right dominant double aortic arch (102).

The diagnosis of double arch with both arches patent can sometimes be made convincingly from the plain chest roentgenogram. The tracheal air column is indented by the more superior, right-sided arch and the more inferior left arch. In the lateral view, the right arch can be seen to indent the trachea posteriorly. These findings may be more obvious with barium esophagography. However, confirmation by echocardiography, angiography, or MRI is desirable because the two arches may be unequal in caliber and it is important to identify the hypoplastic segment in order to divide it. In addition, a web-like coarctation of one arch may not be detectable by the surgeon from the external appearance of the vessel (103). Suprasternal imaging (104) permits the most extensive echocardiographic visualization of the two arches; whereas subcostal (105) and high parasternal imaging (106) rely more on deductive interpretation. While statistically the left arch is much more likely to be hypoplastic than the right, numerous exceptions to that rule necessitate detailed evaluation of each case. MRI provides information both noninvasively and together with the important spatial relationships of the vessels, trachea, and esophagus to better permit surgical planning (107). Furthermore, when both arches are widely patent, velocity mapping permits quantification of flow in the two distal arches to determine which arch should be divided.

Surgical division of the vascular ring is indicated in any patient who is symptomatic with airway or esophageal compression or in a patient undergoing surgery for intracardiac disease. The ring should be divided in its smaller limb, usually but not always the left. The decision to divide between left carotid and left subclavian or distal to the left subclavian is usually determined by accessibility and the length of the particular segment. In the absence of an accompanying conotruncal anomaly with a large VSD, a ductus arteriosus must have been present prenatally. While the presence of a ductus or ligamentum does not appear to contribute to the

severity of tracheal compression by the vascular ring, its importance lies in the surgical management. If the arch is divided but the ligamentum remains intact, there may still be a vascular ring. Thus the surgeon must dissect down to the level of the trachea to be sure that all vascular contributors to a ring have been divided.

PERSISTENT FIFTH AORTIC ARCH

Persistent fifth aortic arch was first reported in man by Van Praagh and Van Praagh (108) in 1969 as a double-lumen aortic arch in which both arches appear on the same side of the trachea, as opposed to double aortic arch in which the two are on opposite sides of the trachea. Since the initial report at least one other variation has been noted resulting in the following subcategorization of this rare anomaly: 1) double-lumen aortic arch with both lumina patent (Figs. 33.1C and 33.2) atresia or interruption of the superior arch with patent inferior (persistent fifth) arch—common origin of all brachiocephalic vessels from the ascending aorta (Fig. 33.19A). More recently, an intermediate form has been recognized with a hypoplastic but patent superior arch (109). Double-lumen aortic arch, in which a “subway” vessel occurs beneath the normal aortic (embryonic fourth) arch, appears to be the more common of the two types (110). This inferior arch extends from the innominate artery to a point opposite the takeoff of the left subclavian artery, just proximal to the ductus arteriosus or its remnant. While frequently associated with major cardiac anomalies, it can be an incidental finding without clinical significance (111,112). Cases of atresia or interruption of the superior arch, with a single arterial trunk giving rise to all four brachiocephalic arteries, have had coarctation of the aorta as the cause for presentation (110). Similarly, the intermediate type with superior arch hypoplasia also presented with coarctation of the inferior arch (109), although we have seen a case with a widely patent inferior arch.

Figure 33.19. Persistent fifth aortic arch. A: Left lateral view of 3-D shaded surface display from MRI of atretic fourth arch type. Note coarctation of fifth arch distally. At surgery, an atretic strand attaching the inferior aspect of the left subclavian artery (LSCA) to descending aorta (D Ao) beyond the coarctation was found. B: Embryonic arch diagram of the case in (A).

Figure 33.19. (Continued) C: Left lateral view of 3-D shaded surface display from MRI of double-lumen-type persistent fifth aortic arch. Note the trachea (T) behind both the embryonic fourth (IV) and fifth (V) arches. Incidentally, there is separate origin of the left vertebral artery (L Vert) from the normal fourth arch. D: Embryonic arch diagram of case in (C).

Embryology

While some animals have been noted to have all six pairs of branchial arches during embryonic development, the fifth pair is often seen as only incomplete arches in man (13), implying a brief appearance with no remnant in the definitive arch system. In order to understand the contribution of a persistent fifth arch to the development of the definitive arch, a modification to the hypothetical double arch is necessary (Fig. 33.19B,D). In cases of double-lumen aortic arch, the fourth arch persists as the superior arch connecting trunco-aortic sac to dorsal aorta, and the fifth (inferior) arch does the same (Fig. 33.19D). With atresia or interruption of the superior arch, the fourth arch serves as the connection between carotid and subclavian artery, similar to an innominate artery, but ipsilateral to the definitive arch, which is the fifth arch. The portion of the dorsal aorta between the entrance of the fourth and fifth arches is atretic or disappears completely (Fig. 33.19B).

Diagnosis and Management

Double-lumen aortic arch has been recognized by angiography, by echocardiography, or at postmortem examination, with the appearance of a subway vessel beneath the normal arch. This can be seen with MRI as well, in coronal or off-axis sagittal (candy cane) sections, since axial slices have to be thin enough to resolve the small gap between the two arches (112). In atresia or interruption of the superior arch, there is the appearance of a truly common brachiocephalic trunk in which all four arch vessels, including the left subclavian artery, arise from a single vessel (Fig. 33.19A). In this situation, the branching pattern alone is the indication of a persistent fifth arch since the atretic dorsal aortic extension of the fourth arch cannot be visualized. However, at surgery for repair of coarctation of

the aorta (distal to the fifth arch), an atretic strand connecting the left subclavian artery to the descending aorta may be seen. There appears to be no other plausible explanation for such a branching pattern. Without additional coarctation of the existing aorta, these two arch anomalies alone have no physiologic significance.

INTERRUPTED AORTIC ARCH

Interrupted, or congenitally absent, aortic arch is defined as a complete separation of ascending and descending aorta. It comprises several different anomalies that generally relate to the pattern of branching of the brachiocephalic arteries. There are at least nine theoretically possible branching patterns. Celoria and Patton (113) classified these as type A if the interruption were distal to the left subclavian artery, type B if between carotid and subclavian arteries, and type C if between carotid arteries. However, these types may be further subcategorized (114) and definitions generalized to include both right and left arch patterns as follows:

- A. Interruption distal to that subclavian artery that is ipsilateral to second carotid artery (i.e., if first carotid right, interruption distal to left subclavian artery)
 1. Without retroesophageal or isolated subclavian artery
 2. With retroesophageal subclavian artery
 3. With isolated subclavian artery
- B. Interruption between second carotid and ipsilateral subclavian artery.
 1. Without retroesophageal or isolated subclavian artery
 2. With retroesophageal subclavian artery (i.e., both carotid arteries proximal, both subclavians distal) (Fig. 33.1)
 3. With isolated subclavian artery

C. Interruption between carotid arteries

1. Without retroesophageal or isolated subclavian artery
2. With retroesophageal subclavian artery
3. With isolated subclavian artery

The order of brachiocephalic artery branching suggests a right or left aortic arch pattern following the conventions of noninterrupted arches: in general, the first branch of the aorta proximal to the interruption contains the carotid artery *opposite* the side of the presumptive arch; a retroesophageal or isolated subclavian artery is always *opposite* the side of the presumptive arch. The significance of sidedness of the presumptive arch in cases of interruption is the finding that interrupted “right” aortic arch is apparently seen only in association with DiGeorge syndrome (115).

Type A interruptions tend to occur with aorticopulmonary septal defect and intact ventricular septum (116); they are seen in a disproportionately large subgroup of patients with transposition of the great arteries and interrupted aortic arch (114). Type B interruptions are much more common than type A and usually have a conotruncal anomaly with normally aligned great arteries in which there is a large malalignment-type VSD associated with posterior displacement of the infundibular septum and subaortic obstruction. Those patients with DiGeorge syndrome and interruption have type B. Type C interruption is quite rare, permitting no general conclusions about associations.

Embryology

The etiology of interrupted aortic arches can be thought of in terms similar to those that describe the formation of the other arch anomalies discussed above. Type A interruptions show involution of both dorsal aortae distal to the fourth arches and proximal to the persistent sixth arch that supplies the descending aorta in place of the fourth arch (Fig. 33.20C). Type B interruptions show involution of one fourth arch and one dorsal aorta between arches four and six (Fig. 33.20D), or, in the frequent variant with both subclavian arteries distal to the interruption, involution of both fourth arches and the sixth arch contralateral to the descending aorta (Fig. 33.20B). Type C interruption entails involution of one limb of the truncus arteriosus and its associated proximal third arch and entire fourth arch with persistence of the normally involuted dorsal aorta between arches three and four, the so-called ductus caroticus (Fig. 33.20E).

Virtually all cases of interruption between carotid and subclavian arteries (type B) are associated with a conotruncal anomaly in which hypoplasia of the subaortic region causes subaortic obstruction and a conal septal malalignment type of VSD (117). The pathophysiology of the interruption is thought to be an absolute decrease in left ventricular output to the ascending aorta (due to the combination of outflow obstruction and VSD) with maintenance of normal fetal cerebral perfusion resulting in a relatively large decrease in flow through the aortic arches beyond the takeoff of one or both carotid arteries. The contributing factors that determine precisely which combination of arch involutions occur in each case are not understood. In a large series of cases with DiGeorge syndrome (118), 43% were found to have type B interrupted aortic arch, and 68% of interrupted arch patients had DiGeorge syndrome. This contrasts with truncus arteriosus communis in which comparable figures were 34% and 33%, respectively. Again, we see the predisposition to fourth arch abnormality in 22q11 patients. Cases in which subaortic obstruction is not present to explain arch involution are not well understood but may well relate to primary neural crest cells' direct influence on the aortic arches themselves.

Diagnosis and Management

These patients typically present, like other ductal-dependent left heart obstructive lesions, with acute cardiovascular collapse or heart failure after spontaneous closure of the ductus arteriosus in the first days of life. Initial management entails fluid resuscitation, induction and maintenance of ductal patency with prostaglandin E₁, and establishment of stable hemodynamics, with inotropic support if necessary. Physical findings of pulse discrepancy, depending upon branching pattern, are only helpful after restoration of satisfactory cardiac output. Absence of all limb pulses suggests interruption type B with anomalous subclavian artery, that is, both carotid arteries proximal, both subclavians distal to the interruption. Strong carotid pulses help to differentiate interrupted arch from critical aortic stenosis in which all pulses are diminished. Differential cyanosis (pink upper body, blue lower body) while theoretically possible is uncommonly seen since pulmonary arterial blood (hence ductal blood) is relatively highly saturated due to the large left-to-right shunt through the VSD. Currently, 2-D echocardiography is the most important tool for diagnostic imaging of interrupted arch. The diagnosis should be suspected from the marked discrepancy in size between ascending aorta and main pulmonary artery (119) with subcostal frontal imaging, in the presence of the typical malalignment-type VSD with posterior deviation of the infundibular (conal) septum, best visualized in the parasternal long-axis view. Imaging of the arch entails determination of the branching pattern and notation of patency of the arch from suprasternal or high parasternal imaging (120). The smooth superior course of the carotid artery origins, especially in type B interruptions, in contrast to the usual posterior course of an intact aortic arch, is a further clue to the presence of interruption. Angiography is still used in many centers to confirm the diagnosis of interrupted aortic arch; however, torrential flow through a VSD makes it difficult to obtain high-quality imaging of the ascending aorta in order to distinguish between interruption and severe arch hypoplasia. Interruption can be diagnosed consistently by angiography when both carotid arteries arise proximal to and both subclavian arteries distal to the interruption (and ductus). The wide separation of carotid arteries from descending aorta unequivocally demonstrates interruption. Three-dimensional reconstruction from MRI can demonstrate the branching pattern and the separation between proximal and distal aorta (Fig. 33.20A).

The surgical approach to treatment depends on the degree of subaortic obstruction. Subaortic diameters of 5 to 6 mm or greater seem to be compatible with primary intracardiac repair, namely patch closure of the VSD and plus aortic arch reconstruction. Subaortic regions of 3 mm or less are inadequate to support normal cardiac output in a full-term infant. In the case of normally aligned great arteries the subaortic obstruction must be bypassed. The preferred method is to associate the proximal main pulmonary artery with ascending aorta using homograft augmentation to complete the aortic reconstruction, similar to that employed for hypoplastic left heart syndrome (Norwood operation) (121,122). Pulmonary blood flow is provided by a Gore-Tex tube graft from the reconstructed aorta if the VSD is left open, or by a right ventricle-to-pulmonary artery confluence conduit if the ventricles are separated by a baffle from left ventricle to pulmonary valve via the VSD. When interrupted aortic arch is associated with transposition of the great arteries, arterial switch operation is combined with transannular patch across the neopulmonary outflow. Pulmonary artery banding is not a satisfactory palliation of VSD with interrupted aortic arch, because it frequently results in biventricular hypertrophy with progressive subaortic stenosis thus complicating definitive repair by any method at a later date.

Figure 33.20. Interrupted aortic arch. **A:** Left anterior oblique view with slight cranial angulation of 3-D shaded surface display from MRI of type B interruption of the aorta with retroesophageal right subclavian artery. A Ao gives rise to RCA and LCA. PDA connects pulmonary artery (blue) with D Ao, which gives rise to RSCA and LSCL. Translucency of pulmonary artery and PDA renderings permits appreciation of separation of proximal and distal aortic components. **B:** Embryonic arch diagram of subtype shown in (A) with absence of both fourth arches and one sixth arch. **C–E:** Embryonic arch diagrams of types A, B, and C interruption, respectively, without retroesophageal or isolated subclavian arteries.

The aortic arch itself can almost always be reconstructed by liberal dissection around the two arch components with direct anastomosis of the two ends (123) plus homograft augmentation of the reconstructed arch when necessary to achieve adequate arch size. Artificial tube grafts connecting proximal and distal aorta should be avoided in the initial operation in infancy, if possible, since they are rapidly outgrown, and with fibrous tissue encasement of the native aorta, complicate primary end-to-end anastomosis at a later date.

OTHER ANOMALIES OF THE AORTIC ARCH SYSTEM

Anomalous Origin of the Pulmonary Artery from the Ascending Aorta

Anomalous pulmonary artery branch arising from the ascending aorta in the presence of a main pulmonary artery arising separately from the heart is a rare anomaly. While the term “hemitruncus” has been used, this lesion should be distinguished from true truncus arteriosus communis with only one pulmonary artery branch arising in common with the ascending aorta, and the other arising from a ductus or systemic collateral vessel from the descending aorta.

By far the more common form is anomalous origin of the RPA, seen in 82% of 108 cases of an excellent review by Kutsche and Van Mierop (124). All had left aortic arch; many had patent ductus arteriosus; few had tetralogy of Fallot. Interrupted aortic arch distal to the left subclavian artery or coarctation of the aorta was present in 14% of those where the pulmonary artery arose just above the aortic valve, and 8/11 of those had an aorticopulmonary septal defect. In contrast, anomalous origin of the left pulmonary artery was associated with tetralogy of Fallot in 74%, and in all cases had either tetralogy or right aortic arch or both. No cases of aorticopulmonary septal defect or interrupted aortic arch were present.

Embryology

The rather dramatic difference in associations between anomalous left and RPA origins suggests different embryologic mechanisms. Kutsche and Van Mierop (124) propose that in anomalous origin of the RPA, the embryonic branch pulmonary artery joins the trunco-aortic sac (at its right side) but fails in leftward migration to reach the main pulmonary artery portion before septation occurs. They point out that this probably accounts for the significant incidence of aorticopulmonary septal defect. The mechanism of anomalous origin of the left pulmonary artery may be failure of the embryonic branch pulmonary artery to join the trunco-aortic sac (or subsequent separation from it) in association with absence of the left sixth (ductal) arch and perhaps persistence of the left fifth arch, whereby the left pulmonary artery becomes associated with the ascending aorta.

Diagnosis and Management

The clinical presentation of anomalous origin of a pulmonary artery branch from the ascending aorta is predominantly that of congestive heart failure (CHF) in infancy followed by the development of pulmonary vascular disease as early as 6 months of age, if unrepaired. In some patients, there may be an abbreviated (or no) period of clinical heart failure, in which case they may go on to develop pulmonary vascular obstructive disease without warning. While many have a significant systolic murmur from turbulent, increased pulmonary blood flow, some have little or no murmur and only a loud, narrowly

split or single second heart sound to suggest the abnormality. The above findings may be tempered by the relatively infrequent association with other major anomalies such as tetralogy of Fallot or interrupted aortic arch.

The chest roentgenogram may show differential pulmonary blood flow, especially when superimposed on decreased flow in association with tetralogy of Fallot. Echocardiography is diagnostic, but one must be aware of the potential for mistaking RPA merging posteriorly with aorta for normal confluence with main pulmonary artery when using a subcostal frontal sweep. Imaging in multiple views including parasternal short axis permits differentiation of the pulmonary artery bifurcation from the juncture of RPA with ascending aorta. In the case of the very uncommon origin of left pulmonary artery, the rule of thumb is to carefully search for all possible origins of both pulmonary artery branches in the face of tetralogy of Fallot. The more lateral origin of the left pulmonary artery from the ascending aorta also makes imaging of this abnormality easier. Cardiac catheterization usually shows pulmonary hypertension in both pulmonary arteries, though only one can be entered from the right ventricle via the main pulmonary artery. Angiographic demonstration is possible with a left ventriculogram but requires an ascending aortogram if there is a VSD. In patients with unexplained pulmonary hypertension, aortic root injection to rule out origin of a pulmonary artery branch from the ascending aorta or the physiologically similar aorticopulmonary septal defect should be considered. While MRI can be diagnostic, at present it cannot be used to quantify pulmonary vascular resistance. Treatment consists of surgical division of the anomalously connected pulmonary artery branch and anastomosis directly, or with a graft, to the main pulmonary artery. This should be carried out as early as possible to avoid the development of pulmonary vascular disease.

Anomalous Origin of the Left Pulmonary Artery from the Right Pulmonary Artery

Origin of the left pulmonary artery from the RPA, also known as anomalous left pulmonary artery, or pulmonary artery sling (125), is a rare anomaly in which the lower trachea is partially surrounded by vascular structures: the left pulmonary artery arising as a very proximal branch of the right loops around the trachea. It is the only situation in which a major vascular structure passes between the trachea and esophagus. Pulmonary sling is frequently associated with complete cartilaginous rings in the distal trachea (126) resulting in tracheal stenosis that may require direct surgical treatment in addition to relief from vascular compression. It usually appears as an isolated abnormality but can be associated with other congenital cardiac defects, including tetralogy of Fallot (127).

Embryology

The distal pulmonary arteries normally arise from their respective lung buds and join the pulmonary artery portion of the trunco-aortic sac separately. If the two distal arteries join each other by incorporation of potential vascular islets from the splanchnic bed before becoming incorporated into the trunco-aortic sac, one possibility is that the left pulmonary artery would pass behind the trachea before making this juncture. This would result in pulmonary artery sling. If it passed in front of the trachea, this would be indistinguishable from the normal situation.

Diagnosis and Management

These patients typically present with severe respiratory distress and stridor although milder forms do exist and may be identified incidentally during imaging for another cardiovascular

anomaly. Sometimes, the respiratory distress can be exaggerated by right lung emphysema (128). Barium swallow, when classical (Fig. 33.1), is diagnostic if one can rule out mediastinal tumor. However, nondiagnostic barium swallows are common, and more definitive testing with echocardiography, angiocardiology, CT, or MRI (Fig. 33.21B–E) is usually necessary to ensure the accuracy of the diagnosis. Symptomatic patients should be evaluated by bronchoscopy at the time of surgical repair because of the frequent association of complete cartilaginous rings. The usual surgical approach is division of the left pulmonary artery from the right and reanastomosis in front of the trachea. Alternatively, Jonas et al. (129) have recommended leaving the pulmonary artery and its branches intact while transecting the trachea, mobilizing it behind the pulmonary artery bifurcation and reanastomosing it. If complete cartilaginous tracheal rings are present, tracheal reconstruction may also be necessary. The latter approach is more amenable in that case since the trachea is already opened.

Innominate Artery Compression of the Trachea

Innominate artery compression of the trachea or so-called anomalous innominate artery is a poorly understood abnormality in which there is anterior compression of the trachea at the point where it is crossed by the innominate artery (Fig. 33.22). Some have thought this to be due to a more distal, that is, leftward, takeoff of the innominate artery from the aortic arch; however, 3-D reconstructions from MRI have not demonstrated any consistent abnormality of the aorta or its branching pattern. The presumed abnormality is tracheomalacia, whether idiopathic or in association with tracheoesophageal fistula (130), with the innominate artery in the vicinity of the malacic segment of trachea. The diagnosis is suspected when signs of severe inspiratory and expiratory stridor, usually in a 2- to 6-month-old child, are associated with anterior indentation of the tracheal air column on lateral chest roentgenogram. However, vascular rings should

Anomalous origin of left pulmonary artery from RPA (sling). **A:** Barium esophagram showing classical anterior indentation. **B,C:** Consecutive images from CT scan of another patient, showing left pulmonary artery (LPA) looping around a small distal trachea (T) but anterior to the esophagus (E) with high signal from a nasogastric tube. (*Continued*)

Figure 33.21. (Continued) D: 3-D surface display from gadolinium-enhanced MRI of the right heart from a different patient than (A–C). Direct cranial view showing the right ventricle (RV) and main pulmonary artery (MPA) giving rise to the RPA. Note the left pulmonary artery (LPA) taking off from the RPA and looping back around the trachea in a tight hairpin turn. E: Posterior view of the same patient as in (D). Again it is clear that the LPA arises from the RPA.

be ruled out with at least a barium esophagram. Simultaneous visualization of the innominate artery and the trachea is afforded by MRI and is shown dramatically with 3-D reconstruction (Fig. 33.1). Treatment usually entails waiting for the tracheomalacia to resolve, typically by age 2 years; however, in cases associated with apnea or repeated lower respiratory infections, surgical sectioning of the innominate artery and reimplantation more proximally, that is, rightward in the aorta may be helpful. In limited cases, suspension from the sternum has been used, but there is often little room behind the sternum to relieve pressure on the trachea because of decreased AP dimension of the chest.

VASCULAR ANOMALIES

Descriptions of some vascular anomalies refer to Greek mythology as *caput medusae*, or a radial orientation of small blood vessels that resemble the hair of Medusa. Writings of Greek and Arab physicians dating back to the 6th century include surgical descriptions of arterial aneurysms in the setting of trauma (131). In 1761, Hunter described two cases of arteriovenous (AV) connections and the physical exam auscultation finding as “as if there was a blast of air through a small hole and interrupted, answering precisely and constantly to the stroke of the heart or diastole of the artery” (132). Following these descriptions, numerous case reports and case series presented arteriovenous malformations (AVMs) in various organ systems, including the liver, brain, and lungs and their physiologic effects (133–136). Elaborate, often confusing nomenclature developed. More recently, detailed investigations into the genetics, physiology, and natural history of vascular anomalies have broadened our understanding of the wide array of defects and have led to clinically applicable classification systems.

EMBRYOLOGY AND PATHOGENESIS

The vascular system is formed well before the heart starts beating in the embryo. Vasculogenesis begins with angioblast formation from mesoderm. These angioblasts differentiate into endothelial cells that then form blood vessels including the dorsal aorta (137). Thus, differences between arteries and veins exist early on in embryogenesis. Studies on tumor angiogenesis (formation of new vessels from existing vasculature) in the 1970s led to the discovery of critical proteins that stimulate vascular development, including basic fibroblast growth factor (bFGF) and vascular endothelial growth factor (VEGF), among others (138). Members of the fibroblast growth factor family stimulate angioblast formation from mesoderm. Disruption of receptors for VEGF and deficiency of VEGF appears to interfere with late stage of vascular development with abnormal vessel wall development and with differentiation of endothelial cells leading to impaired capillary vessel formation (139–141). Tyrosine kinases are believed to aid in the assembly

of nonendothelial components of the blood vessel wall (142). Interestingly, genetic mapping in two families with venous malformations revealed mutations in tyrosine receptors (143).

CLASSIFICATION

There were several reports dating back to the 1800s (Virchow [1863] and Wegner [1877]) that described various features of vascular anomalies but many of them had inconsistent terminology (144). A distinct classification system was described in 1982 based on the biologic behavior and histopathology (145). In this system, vascular malformations are differentiated from hemangiomas. Vascular malformations are usually recognized at birth, have a normal endothelial cell cycle, grow with the child, and show no signs of spontaneous regression. Within the classification of vascular malformations, there are fast flow lesions (arterial malformations, AVMs, and fistulas) and slow flow lesions (venous, capillary, lymphatic, and glomuvenous malformations) (Table 33.2) (146). Hemangiomas, in contrast, are vascular “tumors” with proliferating, involuting, and involuted phases. Only a certain percentage of hemangiomas are present at birth, but they do grow rapidly over the first 2 years of life.

Although there are several types of vascular anomalies that can occur, this chapter emphasizes the abnormalities that typically have cardiovascular manifestations: (a) systemic arterial malformations (b) pulmonary arterial malformations, (c) hemangiomas, and other vascular malformations.

SYSTEMIC ARTERIAL MALFORMATIONS

Systemic arterial malformations include AVMs and arteriovenous fistulas (AVFs). These malformations can develop in various organ systems including the brain, liver, skin, and extremities. Systemic arterial malformations are most often congenital but acquired lesions can develop from trauma, infection, and surgery (147–150). Clinical presentation depends on the location and degree of shunting. The Schobinger staging system has been used to describe the four stages through which AVMs progress (Table 33.3) (151). In large, fast-flow lesions, signs and symptoms of heart failure can develop (Stage 4) and can mimic congenital heart disease. Specific malformations where heart

TABLE 33.3 Clinical Staging of AV Malformations Schobinger Staging (151)

Stage	Description (Typical Age)
1	Asymptomatic (birth—adolescence)
2	Expansion with invasion of deep structures (begins during adolescence)
3	Deep destruction: necrosis, ulceration, pain, and hemorrhage (years after progressive worsening)
4	High-output cardiac failure

failure has been described include vein of Galen malformations, hepatic AVMs, thoracic AVMs, and lower extremity AVMs.

Prevalence

There are numerous types of systemic arterial malformations with varying prevalence, but in general these defects are rare. Vein of Galen malformations occur in <1 in 25,000 live births (152). In adults, the prevalence of brain AVMs vary between 15 and 18 per 100,000 per person years (153,154). Most arterial malformations are sporadic, but there are particular syndromes associated with certain types of AVMs. Hereditary hemorrhagic telangiectasia (HHT) and hereditary neurocutaneous angiomatous malformations, for example, are associated with brain AVMs (155).

Pathology and Pathogenesis

The formation of blood and lymphatic vessels involve vasculogenesis, angiogenesis, and lymphangiogenesis. Although the exact mechanisms of AVM formation are largely unknown, studies of the gene defects of inherited diseases associated with AVMs have provided valuable insight into the pathogenesis of these malformations (156). See section on embryology and pathogenesis for further details.

Pathologic findings in AVMs include a nidus of tortuous vessels that connect feeding arteries to veins without a capillary bed interface. These vessels appear to have chronic changes and are nonfunctioning. Both the connecting arteries and veins demonstrate muscularization of the walls (157).

HHT is highly associated with AVMs in many organ systems and provides insight into the molecular changes leading to AVM formation. Endoglin, a receptor for the TGF- β family of ligands, is found on endothelial cells. Patients with HHT-1 have mutations in endoglin. Deficiency in endoglin along with angiogenic stimulus promotes an abnormal increase in endothelial cell proliferation and resultant AVM formation in a mouse model (158). This mechanism has also been implicated in sporadic cerebral AVMs (159). A high-flow state and resultant shear forces also promote muscularization of the veins within the AVMs, contributing further to the starkly abnormal appearance of these blood vessels (160).

AVMs can be found in the brain, head/neck, limbs, trunk, and viscera. These are fast-flow malformations and can lead to high-output heart failure, which is an indication for treatment.

In infants and children, central nervous system AVMs include the vein of Galen malformation, now commonly referred to as vein of Galen aneurysmal malformations (VGAM). This malformation can cause significant morbidity and mortality related to the neurologic and cardiovascular effects. One of the highest-risk groups are neonates with VGAM that present

TABLE 33.2 Types of Vascular Malformations

Vascular Malformations		
	Slow-Flow	Fast-Flow
Simple	Capillary	Arterial
	Lymphatic	
	Venous	
	Glomuvenous	
Combined	Lymphatic venous	AV
	Capillary-lymphatic-venous	Capillary-AV
	Capillary-venous	AVF

Adapted from Huang JT, Liang MG. Vascular malformations. *Pediatr Clin North Am* 2010;57:1091–1110.

with high-output heart failure that can progress to multiorgan system failure and death. VGAM has been associated with congenital heart defects. Published reports note sinus venosus atrial septal defects and coarctation of the aorta to be relatively more prevalent than other cardiac defects in patients with VGAM. The association of these defects to VGAM may be due to (a) the relatively increased blood flow returning from the superior vena cava (SVC) and possible interruption of the formation of the sinus venosus septum and (b) increased flow across the ductus arteriosus and decreased flow across the isthmus (161,162).

Thoracic AVF/AVMs have only been described in the literature as case reports. Connections between the subclavian artery and innominate vein, the internal carotid arteries, the aorta, and hemiazygos vein and between the subclavian artery and the SVC have all been reported (163–167).

Arterial malformations of the lower extremity can be high-flow lesions, as is the case with Parkes Weber Syndrome. This syndrome is defined by overgrowth of the extremity with multiple AV fistulas along that extremity. The fistulas usually develop around puberty or after trauma and can be complicated by CHF (168).

Physiology and Clinical Manifestations

Clinical manifestations of AVMs are largely dependent on the size of the malformation and degree of left-to-right shunting. The more extensive the AV connections, the greater the amount of shunting and the larger the hemodynamic burden on the cardiopulmonary system. For the purposes of this section, we focus on the diagnosis of patients with large systemic AV shunts who are experiencing high-output cardiac failure.

The VGAM can produce significant morbidity and mortality related to neurologic and cardiovascular manifestations. In utero, fetuses can experience a range of hemodynamic effects due to VGAM including mild cardiac insufficiency to fetal hydrops. While the placenta provides a low resistance circuit to redirect blood flow away from the AVM, after birth, elimination of the placenta redistributes blood flow. Now, the obligatory (independent of pulmonary vascular resistance) VGAM shunt increases SVC flow and right atrial and right ventricular enlargement soon develop. There can be a right-to-left atrial shunt, a poorly contracting and dilated right ventricle, and antegrade systolic flow in the ductus arteriosus shortly after birth due to a high pulmonary vascular resistance (169,170).

Neonates and young infants with these cardiovascular changes present with a history of respiratory distress, failure to thrive, and sometimes lethargy or seizure. In particular, cyanosis and pulmonary hypertension can complicate the heart failure symptoms and may mimic a significant congenital heart defect, potentially delaying the diagnosis of VGAM. Physical exam reveals tachypnea, tachycardia, and cardiac murmur, and auscultation over the anterior fontanelle sometimes reveals a continuous murmur due to the increased blood flow through the AVM (169,171).

Older infants may present with macrocephaly, leading to hydrocephalus and seizures. Long-standing cerebral venous hypertension can lead to developmental delay. Older children and adults present with headaches or intracranial hemorrhage (172).

Thoracic AVMs present either in childhood with a continuous murmur or with symptoms and signs of high-output heart failure due to a significant left-to-right shunt. In addition to the murmur, a widened pulse pressure, bounding pulses, hyperdynamic precordium, and prominent S_2 can be found. There have been reports of fetal presentation of large thoracic AVMs with hydrops and high-output failure (173).

Electrocardiogram and Radiography

Electrocardiographic findings of infants with large AVMs are nonspecific and may show sinus tachycardia, right ventricular

or biventricular hypertrophy. Occasionally signs of ischemia, with ST segment changes are present (152,174). In older children who present with systemic AVMs, the electrocardiogram (ECG) may be normal or demonstrate ventricular hypertrophy. Infants with large systemic AVMs will have cardiomegaly on chest radiography, especially marked right atrial and right ventricular enlargement.

Ultrasound

Ultrasound is extremely helpful in the diagnosis of systemic AVMs. These malformations appear heterogeneous with large feeding vessels often seen by 2-D imaging. Color Doppler interrogation shows high vessel density with high-velocity systolic flow and low resistance. Draining veins appear dilated and pulsatile (175).

Echocardiography

Echocardiographic findings include cardiomegaly with markedly enlarged right heart with leftward displacement of the interventricular and atrial septae. There is often tricuspid valve regurgitation with a high-velocity jet, consistent with elevated right-ventricular pressure. Flow across the patent foramen ovale is often right-to-left. In the cases of VGAM, the proximal aorta and its branches are dilated and retrograde diastolic flow can be seen in the descending thoracic aorta. High-velocity flow is observed in the SVC, main pulmonary artery, and ascending aorta secondary to the large volume of blood flow from the shunt (169).

Cardiac Catheterization and Angiography

Patients do not commonly undergo diagnostic cardiac catheterization in the presence of systemic AVMs. Those who do, have oximetry data that shows a high-cardiac output state (low arterial venous oxygen difference) and can have a difference in saturation between the inferior vena cava (IVC) and SVC depending on the site of the AVM (176,177). Hemodynamic measurements can show elevated ventricular end-diastolic pressure in presence of CHF and elevated pulmonary arterial pressure in neonates with large AVMs.

Angiography is important in definition and management of systemic AVM. Angiograms show enlarged arterial feeding vessels with rapid transit time across the AVM, followed by dilated venous drainage of the malformation (178). (Fig. 33.1) Selective angiography at the site of the AVM can define size, number, and location of feeding vessels to plan for possible intervention.

Other Imaging

By CT, AVMs appear as enhancing lesions with several afferent and efferent vessels without persistent tissue staining. MRI shows low signal intensity secondary to a flow void phenomenon of the rapid/turbulent flow (178). Magnetic resonance venograms are an accurate, noninvasive method of imaging systemic AVMs and can be a desirable alternative to angiography if immediate intervention is not needed (Fig. 33.23).

Differential Diagnosis

In the setting of heart failure symptoms with cardiac enlargement on adjunct testing and without evidence of an intracardiac shunt, an AVM must be considered. The differential diagnosis of systemic AVM includes congenital heart defects, other vascular malformations, vascular tumors, and rarely other neoplasms. Auscultation and noninvasive imaging can aid in differentiating the above diagnoses (179).

Figure 33.23. Systemic arterial malformations. **A:** Lateral view of a left vertebral angiogram. There is a large tortuous vertebral artery supplying branches to fill the aneurysmal vein (*unfilled arrow*). The enlarged VGAM (*filled arrow*) drains into a dilated straight sinus (*asterisk*). **B:** Three-Dimensional time-of-flight MR venogram without contrast demonstrating a similar image to (**A**). Large venous aneurysm is seen draining into dilated vein of Galen, which drains via the dilated venous sinuses to the jugular veins. **C:** Axial source image for 3-D time-of-flight MR. Mixed bright signal is seen within the aneurysm (*thick arrow*). A slice of the dilated vein of Galen is seen (*thin arrow*). Brain and fluid are deemphasized to display high-flow areas as bright signal intensity. **D:** Axial image at same level as (**C**). T1 weighted with high signal intensity within the brain parenchyma. Flow void seen within the venous aneurysm and vein of Galen. The straight sinus (*arrow*) is also dilated secondary to increased venous return. (Images courtesy of Marc Keller, MD, Department of Interventional Radiology, The Children's Hospital of Philadelphia.)

Treatment/Natural history

Initial management of neonates often includes minimizing the cardiovascular effects and damage to other end organs while awaiting more definitive treatment. Inotropic support with

dopamine or dobutamine can worsen cardiac output, but low-dose dopamine has been shown to improve systemic perfusion (152). Administration of milrinone can also be considered as there is evidence that it promotes cerebral vasodilation as well as systemic vasodilation (180). However, there have been

no studies in VGAM. There is also some evidence that prostaglandin administration improves systemic perfusion from systemic vasodilation (170). Failure of intensive care management to stabilize the neonate often leads to early embolization to attempt to reduce the shunt. Even with aggressive management, severe heart failure requiring intubation in the newborn period is usually associated with a poor outcome (172,181).

Although prompt neonatal diagnosis and management of significant VGAM has reduced early mortality, the general prognosis for infants with large cerebral arterial malformations is grave. These patients not only can suffer from heart failure due to a large shunt but also can have significant neurologic sequelae, including seizures, intracranial hemorrhage, and developmental delay.

Surgical excision of systemic AVMs is only possible if the malformation is well circumscribed and accessible. For significant cerebral AVMs, neurosurgical techniques carry mortality between 30% and 90% depending on the age of the patient (182,183). Recently, surgical intervention is reserved for evacuation of intracranial hematomas, treatment of hydrocephalus, and surgical ligation of vessels when transcatheter embolization is not possible.

Transcatheter embolization is now the therapy of choice for significant systemic arterial malformations, including cerebral AVMs. There is a wide variety of agents to treat these malformations depending on the location. For VGAM, chemical agents such as ethanol, *N*-Butyl-2-cyanoacrylate, and ethylene-vinyl alcohol have been most successful. This sclerosant technique targets the high-flow, low-resistance nidus between the arterial and venous system (184). In a large study of 216 patients, utilizing a transfemoral arterial approach to deliver this glue in the fistulous zone, 23 died (10.6%), 20 of the surviving 193 patients (10.4%) were severely delayed, and 143 (74%) were neurologically normal on follow-up (185). Other, smaller series reported similar data (—186–188). Intervention on the feeding arteries by surgical ligation or mechanical agents, such as coils, provides only temporary relief, as collateral vessels ultimately form to continue to feed the direct AV connection (175). Stereotactic radiotherapy also only has a limited role, especially in the neonate.

PULMONARY ARTERIOVENOUS MALFORMATIONS

Pulmonary arteriovenous malformations (PAVMs) are vascular lesions defined by abnormal connections between pulmonary arteries and pulmonary veins (Fig. 33.24). Patients with PAVMs often have systemic AVMs as well. The most common associated diagnosis is HHT, otherwise known as Osler-Weber-Rendu Syndrome. PAVMs can also be seen in patients with pulmonary hypertension, congenital heart defects with single-ventricle physiology and palliation, cystic fibrosis, and severe liver disease (189).

Prevalence

HTT affects about 1 in 5,000 people overall (190). About 15% to 33% of patients with HHT have PAVMs (191). Patients with congenital heart disease defined by single-ventricle physiology and palliated with superior cavopulmonary connection (bidirectional Glenn, BDG) can also develop PAVMs. The overall incidence of PAVM in this population is 15% to 25% and is seen more commonly in patients with heterotaxy and interrupted IVC with azygos continuation (192,193). In addition, patients with complete cavopulmonary connections (Fontan palliation) who have preferential hepatic flow to one lung can manifest PAVMs in the opposite lung (194).

Figure 33.24. Pulmonary AVM. Angiogram in the AP projection in a patient with heterotaxy syndrome who is status post superior cavopulmonary connection. An antegrade catheter courses through the interrupted IVC with azygos continuation and is positioned in the main pulmonary artery (MPA). Injection of contrast into the MPA demonstrates a reticular appearance of the left lung. In addition, there is contrast seen in the left pulmonary veins, while the right lung contrast is still in the arterial phase, indicating decreased transit time in the left lung. Both angiographic findings are consistent with left lung PAVMs.

Pathology and Pathogenesis

The pathologic appearance of PAVMs is similar to AVMs seen elsewhere in the body. Pathology and pathogenesis of AVMs in HHT is outlined above.

PAVMs in the setting of single-ventricle heart defects were initially reported as a late complication after SVC-RPA anastomosis (classic Glenn shunt) (195). In the current era, even with varied surgical approaches to the cavopulmonary anastomosis, some patients continue to develop PAVMs. There is growing evidence that a yet unidentified “hepatic factor” is the putative agent that, when absent in the pulmonary circulation, predisposes to the development of PAVMs (196). Hepatopulmonary syndrome is a condition associated with cirrhotic liver disease where PAVMs can develop. Once patients undergo liver transplantation to resolve their liver failure, the PAVMs have been shown to regress. Similarly, in single-ventricle heart disease palliated by a cavopulmonary anastomosis, PAVMs tend to resolve once hepatic venous flow is directed to the affected lung segments, suggesting a pathophysiology similar to that of hepatopulmonary syndrome. Nonpulsatile flow and preferential blood flow to the lower lobes of the lung are thought to be additional contributors to the development of PAVMs in patients with superocavopulmonary connections (197).

Physiology and Clinical Manifestations

PAVMs promote varying degrees of shunting of deoxygenated blood to the systemic circulation. These abnormal vessels in the lungs bypass the pulmonary capillary bed and hence, oxygenation does not occur. Systemic arterial desaturation

and compensatory polycythemia develop depending on the extent of the PAVMs.

Clinical manifestations of PAVMs include dyspnea, cyanosis, and occasionally hemoptysis. The most common complaint in HHT patients is epistaxis, either spontaneous or with minor trauma (198). Patients with HHT also commonly present with dyspnea on exertion but a large number of patients with HHT may tolerate long-standing hypoxemia without dyspnea (191). Platypnea (improvement in dyspnea when lying supine) has been described and is thought to be secondary to redistribution of pulmonary flow to nondependent regions, away from the regions of the AVMs (198). On physical exam, patients are desaturated by pulse oximetry or can appear cyanotic. These patients can have an audible bruit over the lung fields, which is louder with inspiration and may have clubbing of the extremities.

In the absence of congenital heart disease, the majority of patients with PAVMs can remain asymptomatic until the fourth decade of life. There have been some series that have shown a correlation between symptoms and lesion size (<2cm being asymptomatic) or number, with multiple PAVMs causing more severe symptoms. However, reports have been inconsistent, despite trends supporting that correlation (198). In addition, there have been rare reports of infants presenting with profound cyanosis who are found to have direct RPA to left atrial connections (199). In adults, severe cases can present with massive hemoptysis, hemothorax, or neurologic events (transient ischemic attack, stroke, or cerebral abscess) secondary to right-to-left shunting of septic emboli (200).

Patients with single-ventricle cardiac defects and cavopulmonary anastomosis are asymptomatic initially after their surgery and become progressively cyanotic with decreased arterial oxygen saturation as PAVMs develop. Their chest radiographs show no evidence of parenchymal disease. This constellation of findings should prompt screening for PAVMs in this group of patients (see below) (193,197).

Electrocardiography

ECGs are usually normal in patients with PAVMs. Occasionally, left atrial enlargement and left ventricular hypertrophy can occur, especially in the setting of a direct RPA to left-atrial connection (199).

Radiography

Chest radiographs show abnormalities in the majority of patients with PAVM. The malformations usually appear as discrete, 1- to 5-cm, round or oval masses with uniform density. These masses can be lobulated but have well-defined borders and are more common in the lower lobes. Feeding vessels can also be seen on chest radiography and can range in size from 4 to 7 mm, being as large as 20 mm in some cases (198).

Echocardiography

Based on adult data in patients with HHT, the current recommendation for screening of PAVMs is transthoracic contrast echocardiography with agitated saline (201). During echocardiography, agitated saline is injected in a peripheral vein while imaging the atria and ventricles on apical four-chamber view, for example. Normally, on imaging, acoustic signals (or bubbles) from the agitated saline appear in the right atrium and ventricle immediately after injection and do not appear on the left side of the heart in the absence of a right-to-left shunt because the bubbles dissolve in the pulmonary capillary bed. The appearance of bubbles in the left atrium after several beats indicates the passage of blood through the lungs and into the left atrium without interfacing with the pulmonary capillary

bed and confirms the presence of pulmonary AVMs. This finding also differentiates pulmonary AVMs from an atrial shunt where saline contrast would appear in the left atrium immediately after injection (202). If contrast echocardiography is positive, the diagnosis can be confirmed by CT scan or angiography.

Cardiac Catheterization and Angiography

Although the diagnosis of PAVMs can be made by angiography, cardiac catheterization is usually not the initial diagnostic test of choice in this era of accurate noninvasive diagnostic testing. However, in patients with congenital heart disease and new-onset cyanosis, hemodynamic catheterization and angiography provides important data and can afford a means of treatment.

Hemodynamic assessment of patients with PAVMs reveals pulmonary vein desaturation in the affected lung. It is important to obtain oximetry data from all pulmonary veins to localize the PAVMs. Typically, pulmonary artery pressure, resistance, and output are normal, even in the setting of profound cyanosis and polycythemia (203). Angiographic appearance of PAVMs include rapid transit time from pulmonary arteries to pulmonary veins with a reticular appearance of the lung parenchyma (204) (Fig. 33.1).

Other Imaging

Helical multidetector CT scan of the chest is emerging as the preferred technique for diagnosis and characterization of PAVMs. Intravenous contrast enhances PAVMs and allows differentiation from other lung nodules and characterization of perfusion. Nuclear medicine scans can also be diagnostic. Intravenous injection of radiolabeled albumin particles collect in normal lung: areas not opacified after IV injection represent areas of lung with AV connection. This technique is no longer widely used (191).

Differential Diagnosis

The differential diagnosis of PAVMs includes many forms of cyanotic congenital heart disease, especially those having anomalous return to systemic veins to the left atrium. In single-ventricle heart disease after cavopulmonary connection, increased cyanosis can also occur with systemic venovenous connections that develop from the Glenn pathway and connect either to vessels that drain to the IVC or to the pulmonary veins. The formation of these connections is thought to occur in the setting of elevated pressure in the Glenn connection.

Treatment/Natural History

Growth rates are variable and appear faster in those with HHT than in those without that diagnosis (205). However, the morbidity of untreated AVMs is also significant and include incidence of stroke of 11%, 6.8% incidence of brain abscess, and total morbidity and mortality of 23% (205,206). Definitive indications for treatment of pulmonary arterial malformations include cyanosis, exertional dyspnea, or systemic emboli. Some experts advocate for prophylactic treatment of all PAVMs to prevent potential systemic embolization if the vessel is >3 mm in diameter (197,207). Treatment of PAVMs with smaller feeding vessels (1.5 to 2 mm) can be undertaken if a right-to-left shunt is present and vessels are easily accessible.

Currently, the most widely used therapy is transcatheter embolization of the feeding arteries to the PAVM using coils or detachable balloons. Malformations with large feeding arteries may require device occlusion (191). Surgical treatment for PAVMs has become increasingly uncommon, as catheter-based

techniques have evolved. Surgical lobectomy, segmentectomy, or pneumonectomy is currently reserved for patients with extensive PAVMs that are not amenable to catheter embolization or as an emergent procedure for hemothorax (208).

In patients with single-ventricle heart defects and superior cavopulmonary connections, inclusion of hepatic venous blood to the pulmonary circulation will often cause regression of PAVMs. This resolution occurs after completing the Fontan procedure, hepatic vein inclusion in patients with heterotaxy syndrome and interrupted IVC with azygos continuation, correction of pulmonary artery discontinuity in a Fontan where IVC blood is directed to one lung and PAVMs develop in the other, creation of a brachial AVF, or cardiac transplantation (209–213). Patients with heterotaxy syndrome with interrupted IVC and azygos continuation have been shown to more commonly develop PAVMs after superior cavopulmonary connection (Kawashima) (214). In addition, there is some evidence that patients with interrupted IVC who have hepatic vein inclusions, with conduits on the contralateral side of SVC, are less likely to have resolution of PAVMs. This phenomenon is likely secondary to streaming of hepatic venous blood preferentially to one lung (212). There are efforts to derive computer models of all the possible types of Fontan connections to optimize surgical planning in these patients and reduce the likelihood of persistent PAVMs (215).

HEMANGIOMAS AND OTHER VASCULAR MALFORMATIONS

Historically, the field of vascular anomalies has grappled with classification and nomenclature of very disparate lesions (216). More recently, a biologic classification system has appropriately divided vascular anomalies into vascular tumors, lesions that arise from endothelial hyperplasia, and vascular malformations, lesions that arise by dysmorphogenesis and normal endothelial cell turnover. This system appears to better guide diagnosis, prognosis, and treatment (216). Vascular tumors include hemangiomas, while vascular malformations encompass venous, capillary, and lymphatic malformations.

Prevalence and Pathogenesis

Hemangiomas are the most common vascular tumor, occurring in 4% to 10% of infants. It is a tumor of the endothelium and a model for angiogenesis. These tumors are more common in Caucasians and more frequent in females (3:1). Sixty percent of tumors occur in the head and neck, 25% are found on the trunk, and 15% occur in the extremities. While 80% are single lesions, approximately 20% of hemangiomas are located in multiple cutaneous sites and in other organ systems, specifically the liver, gastrointestinal tract, and brain (144).

Hemangiomas appear a few weeks after birth and grow rapidly. The proliferative phase is highlighted by plump endothelial cells with frequent mitosis and lasts until 1 year of life. bFGF and VEGF are angiogenic proteins that stimulate this endothelial proliferation. Spontaneous slow involution follows from approximately 1 to 7 years of life with normal-appearing endothelial cells in a matrix of “fibrous fatty tissue.” This phase involves endothelial apoptosis and down regulation of angiogenesis. The life cycle of this tumor ends with the involuted phase. Fifty percent of hemangiomas have complete regression by the age of 5 years and 90% by the age of 9 years (217). There are many classification systems based on location and color of hemangiomas (145,218).

As discussed above, vascular malformations are classified according to the type of blood vessel involved: arterial,

Figure 33.25. Cutaneous hemangioma. Large cutaneous hemangiomas on forehead of an infant with multiple cutaneous hemangiomas. The lesion is *bright red, nodular*, and well circumscribed with normal surrounding skin.

AV, capillary, venous, or lymphatic. These malformations are present at birth but may not be clinically evident until later in life depending on the type; they occur equally in males and females (144). In contrast to hemangiomas, vascular malformations enlarge by hypertrophy. Histologic appearance includes normal-appearing endothelial cells and ecstasic vessels (145). These malformations can be classified by their hemodynamic characteristics on angiography (see Table 33.2) as high-flow lesions (arterial, AV) and low-flow lesions (capillary, venous, lymphatic) (144). Syndromes associated with slow-flow vascular malformations include Sturge-Weber, Klippel-Trenaunay, Rubinstein-Taybi, thrombocytopenia-absent radius, Beckwith-Wiedemann, and others. Those associated with fast-flow lesions are Parkes Weber, capillary malformation-AVM, and Cobb syndrome (Fig. 33.25).

Clinical Manifestations

It is often difficult to distinguish hemangiomas from vascular malformations because it is not always apparent whether or not the lesion was present at birth. Vascular lesions, which are not present at birth and show signs of either proliferation or involution are typically hemangiomas. The typical superficial hemangiomas are red and raised (Fig. 33.1). Deeper hemangiomas can be confused with a vascular malformation or other rare tumors. There have been documented cases of hemangiomas diagnosed prenatally and a few cases with hydrops fetalis and heart failure (173). In addition, infants with multiple cutaneous hemangiomas (≥ 5) are more likely to have hepatic hemangiomas (16%). Hepatic hemangiomas can have a variable course from asymptomatic to high-output cardiac failure in rare cases (219). Venous and lymphatic malformations are compressible but high-flow lesions such as arterial or AVMs are typically firm to the touch and do pulsate.

Diagnosis and Treatment

The diagnosis of hemangiomas and vascular malformations can generally be made on history and physical exam. However, noninvasive imaging with ultrasound or MRI should be performed when deeper lesions are suspected to outline the extent of the lesion(s) and ensure there is no organ system involvement.

In most cases, hemangiomas are followed closely and allowed to regress naturally without need for treatment. After regression, a minor blemish may be all that remains. Only

about 10% of hemangiomas are associated with significant symptoms and require treatment. These high-risk lesions tend to occur in the areas of head, neck, airway, eye, lumbosacrum, or liver (220). Treatment is indicated in children with compromised airways, neurologic changes, digestive tract obstruction, bleeding, or ulceration. Medical treatment options include oral corticosteroids, tapered over infancy with 80% to 90% response rate. Interferon- α is a second-line agent for life-threatening hemangiomas (216).

Treatment of cutaneous hemangiomas with the beta-blocker, propranolol was first noted in 2008. An infant, being treated with propranolol for hypertrophic cardiomyopathy, was noted to have coincidental improvement in a

nasal hemangioma (221). This case prompted a study of 11 patients, describing significant improvement in hemangioma appearance 24 hours after initiating propranolol treatment (221). Propranolol is a nonselective β -receptor antagonist, having effect on both β_1 and β_2 receptors. The proposed mechanism of action of propranolol in the setting of hemangiomas is threefold: (a) vasoconstriction, secondary to the blocking of vasodilatory properties of epinephrine, allowing unopposed α_1 stimulation, (b) inhibition of angiogenesis, by blocking of angiogenic growth factors important to hemangioma proliferation, and (c) induction of apoptosis, thought to be regulated through β_1 receptor pathways (217,222).

Figure 33.26. Hepatic hemangiomas. **A:** Chest radiograph of 5-month old with multiple hepatic hemangiomas and high cardiac output state. There is marked cardiomegaly with increased pulmonary vascular markings and hepatomegaly. **B:** Coronal section of T2-weighted abdominal MRI showing multiple homogenous, circular hemangiomas throughout the liver. **C:** Selective angiography of the hepatic artery prior to intervention, demonstrating multiple hemangiomas throughout both lobes of the liver. **D:** Selective angiography of the hepatic artery after particle embolization of liver hemangiomas in the right lobe. There is significant improvement with little contrast seen outside of the normal liver vasculature of the right lobe. The left lobe hemangiomas remain prominent. (Images courtesy of Anne Marie Cahill, M.D. Department of Interventional Radiology, The Children's Hospital of Philadelphia.)

More recent studies have shown propranolol to be effective treatment for complex infantile hemangiomas. These patients are often treated in conjunction with a pediatric cardiologist, given propranolol's potential to cause bradycardia and hypotension, although these side-effects are rare (222). Hypoglycemia is a more commonly observed side effect of propranolol therapy, especially in younger infants (223). Evidence on outcomes after propranolol treatment is lacking given the small studies and case reports available (221,222,Starkey, 2011 #262).

Other modalities for treatment of hemangiomas include cryotherapy, sclerotherapy, surgical resection, and laser therapy. Embolization therapy may be utilized to control heart failure symptoms. This therapy is most often used for hepatic hemangiomas as they have a higher incidence of CHF (216). (Fig. 33.1)

In contrast to hemangiomas, vascular malformations do not generally resolve spontaneously and treatment is less controversial. Laser treatment, embolization therapy, and surgical excision have all been used and the choice depends on the location and extent of the malformation. Low-flow capillary and venous malformations can be addressed with laser therapy, whereas surgery may be indicated in lymphatic malformations. Transcatheter embolization therapy is indicated in high-flow, arterial or arteriovenous malformations.

ACKNOWLEDGMENTS

We would like to thank our colleagues Mark A. Fogel, M.D., Matthew Harris, M.D., and Kevin Whitehead, M.D., Ph.D. for their contribution of many of the 3-D shaded surface displays from MRI; Marc Keller, MD for angiogram and MR images in Figure 33.23; Anne Marie Cahill, M.D. for chest radiograph, MRI, and angiograms in Figure 33.26; and William M. Gottliebson, MD, MS, Division of Cardiology, Cincinnati Children's Hospital Medical Center for the 3-D CT image in Figure 33.16C.

INTRODUCTION

Progressive aortic root dilation has been reported in a number of congenital heart defects, both repaired and unrepaired (1). Following extensive research in this field in the past decades, the thoracic aortic wall is no longer considered as a simple tube but rather a highly sophisticated structure responsive to local hemodynamic changes (2). Inherited connective tissue disorders, such as Marfan disease and bicuspid aortic valve (BAV), have served as aortopathy models, both in terms of pathogenesis and medical management. However, similar aortic wall abnormalities have been reported in a wider range of disparate congenital heart defects, including coarctation of the aorta, tetralogy of Fallot (TOF), and complete transposition of the great arteries (TGA) (Table 34.1). Aortic dilation is usually silent but may produce symptoms of acute aortic dissection or rupture as aneurysm formation progresses. Thus, early identification of aortopathy is important for appropriate follow-up and timely intervention. As life expectancy of patients with congenital heart disease (CHD) increases, several cardiovascular risk factors superimpose on inherent wall abnormalities, and may increase the incidence of aortic complications. The following sections review the most prevalent CHD lesions associated with aortic root abnormalities and the underlying pathology, diagnostic evaluations, and treatment options.

MARFAN SYNDROME

Marfan syndrome (MFS) is a heritable connective tissue disorder resulting from mutations in the fibrillin-1 (FBN1) gene located on chromosome 15 (15q21.1). The estimated prevalence of MFS is 1 in 5,000 to 10,000 live births, affecting both sexes equally (3). Up to 95% of individuals fulfilling the clinical criteria for MFS have a FBN1 mutation (4). Approximately a quarter of affected individuals have *de novo* mutations, with absence of family history of the disease. MFS has an autosomal dominant pattern of inheritance with a high penetrance, affecting almost all allele carriers, but marked phenotypic variability. The syndrome has several manifestations from the skin and the skeletal, cardiovascular, and ocular systems and is considered a prototype model for aortic pathology; practically all affected patients present with aortic dilation or dissection during their lifetime (5). Underlying histologic abnormalities of the aneurysmal aortic wall have been described applying the term “cystic medial necrosis,” characterized by elastic fiber fragmentation, noninflammatory loss of vascular smooth muscle cells (VSMCs), and accumulation of basophilic ground substance within cell-depleted areas in the aortic media (3). However, as described later, these changes are not unique to MFS but can be found in other causes of nonsyndromic thoracic aortic aneurysms (TAA) (6).

Despite the identified causative role of FBN1 mutations, the exact sequence of molecular changes leading to MFS continues to be under investigation. FBN1 is a main structural component of the extracellular microfibrillar network that connects VSMCs to the surrounding elastic fibers, facilitating tissue elasticity (7). At present, more than 1,000 mutations have been described in the FBN1 gene without a clear genotype–phenotype association (3). Mutations in exons 24–32 may be indicators of earlier onset of morbidity in MFS although the latter were not associated with a higher risk of aortic dissection in patients with aortic dilation (8). Due to the established weakness of connective tissue, early theories on the pathogenesis of MFS focused on the structural properties of FBN1. A dominant negative effect was initially suggested, where the mutant allele gives rise to abnormal FBN1 that in turn disrupts the assembly of normal fibrillin polymers (9,10). However, a different study in transgenic mice has exhibited that the mutated protein participates in productive microfibrillar formation (8). Moreover, the addition of a normal allele in the same animal model rescued the aortic phenotype, highlighting the contribution of haploinsufficiency to the disease (11). This raises the possibility that the normal aortic wall lamellar structure can be restored.

More recently, the importance of transforming growth factor beta (TGFβ) in the pathogenesis of MFS has emerged. The TGFβ family of cytokines plays a central role in vascular remodeling and aneurysm formation (2). Mouse models of the disease have shed light on the regulatory functions of fibrillin 1, which controls the bioavailability of TGFβ by binding a latent form of the cytokine. Excessive TGFβ signaling has been shown to play a causal role in aortic root enlargement, mitral valve abnormalities, and emphysema associated with MFS (12–14). More importantly, the administration of TGFβ-neutralizing antibody has led to reversal of the above manifestations (3). The general mechanistic hypothesis for the above findings is that fibrillin 1 deficiency makes sequestered TGFβ more accessible to activation, although mutated forms of the protein can also stimulate TGFβ release (15). The significance of the TGFβ pathway was confirmed with the discovery of a second locus for MFS, termed as Marfan syndrome type II (MFS2), associated with mutations in the transforming growth factor-beta type II receptor (TGFB2) (16). Overall, it is hypothesized that FBN1 deficiency results in altered homeostasis of the extracellular matrix and subsequent increase of TGFβ activity. The exact sequence of succeeding mechanisms leading to aortic wall degeneration remains elusive. However, it has been established that increased elastolysis occurs, with activation of matrix metalloproteinases (MMP-2 and MMP-9), apoptosis of VSMC, and abnormal cell migration (17).

Diagnosis

The diagnosis of MFS is largely based on clinical grounds. Due to the wide range of clinical manifestations, a multidisciplinary approach is required. A definite diagnosis can be made

TABLE 34.1 Commonest Congenital Heart Disease Lesions Associated with Aortic Root Abnormalities

Heart Defect	Location of AoD	Incidence of AoD	Incidence of Dissection	Recommendations for Ao Replacement
MFS	Sinuses of Valsalva (typical location)	<ul style="list-style-type: none"> ■ 35% by 5 y (24) ■ 68% by 19 y (24) 	<ul style="list-style-type: none"> ■ 4.3% in childhood (26) ■ 20% in adolescence (26) 	<ul style="list-style-type: none"> ■ >50 mm ■ accelerated aortic growth (>10 mm/y) ■ Development of aortic regurgitation ■ Need for mitral valve surgery
BAV	Ao root and ascending aorta	<ul style="list-style-type: none"> ■ <19 y, isolated BAV (64) ■ 12% marked AoD ■ 25% moderate AoD 	<ul style="list-style-type: none"> ■ Case reports in adolescents (65) 	<ul style="list-style-type: none"> ■ >50 mm ■ accelerated aortic growth (>10 mm/y) ■ Need for aortic valve surgery with AoD > 45 mm

TABLE 34.2 Revised Ghent Nosology for the Diagnosis of Marfan Syndrome

Revised Ghent Criteria for the Diagnosis of Marfan Syndrome (19)

In the Absence of Family History of MFS:

- (1) Ao ($z \geq 2$) and ectopia lentis
- (2) Ao ($z \geq 2$) and FBN1 mutation
- (3) Ao ($z \geq 2$) and systemic features (≥ 7 points)^a
- (4) Ectopia lentis and FBN1 mutation previously associated with aortic root aneurysm/dissection

In the Presence of Family History of MFS:

- (5) Ectopia lentis
- (6) Systemic features (≥ 7 points)^a
- (7) Ao ($z \geq 2$ above 20 y old, ≥ 3 below 20 y old)

^aNew Scoring of Systemic Features (≥ 7 Points Indicates Systemic Involvement):

- Wrist and thumb sign—3 (wrist or thumb sign—1)
- Pectus carinatum deformity—2 (pectus excavatum or chest asymmetry—1)
- Hindfoot deformity—2 (plain pes planus—1)
- Pneumothorax—2
- Dural ectasia—2
- Protrusio acetabuli—2
- Reduced upper segment/lower segment ratio and increased arm/height and no severe scoliosis—1
- Scoliosis or thoracolumbar kyphosis—1
- Reduced elbow extension—1
- Facial features (3/5)—1 (dolichocephaly, enophthalmos, downslanting palpebral fissures, malar hypoplasia, retrognathia)
- Skin striae—1
- Myopia >3 diopters—1
- Mitral valve prolapse (all types)—1

Special Considerations for Young Individuals (<20 y old):

- (1) Use term “nonspecific connective tissue disorder” in sporadic cases with insufficient systemic features (<7 points) and/or borderline aortic root measurements ($z < 3$) without FBN1 mutation, until follow-up echocardiographic evaluation shows aortic root dilation ($z \geq 3$)
- (2) Use term “potential MFS” in sporadic or familial cases with a FBN1 mutation and Ao $z < 3$, until the aorta reaches threshold
- (3) Neonatal MFS is not considered as a separate category, but represents the severe end of the MFS spectrum

Ao, aortic diameter at the sinuses of Valsalva above indicated z-score or aortic root dissection; FBN1, fibrillin-1 gene mutation; MFS, Marfan syndrome; z, z-score.

^aNew scoring of systemic features.

Modified from Loeys BL, Dietz HC, Braverman AC, et al. The revised Ghent nosology for the Marfan syndrome. *J Med Genet* 2010;47:476–485.

applying the Ghent criteria, which are based on demonstration of symptoms from different organ systems and family history of MFS (3). However, Ghent nosology cannot exclude MFS in children, due to the variability in onset and severity of symptoms in this age group (18). Consequently, long-term follow-up is required in younger patients before a diagnosis can be established. Recently, an international expert board has published a revised Ghent nosology, in which aortic root aneurysm and ectopia lentis are the cardinal features of MFS with a new scoring system for other systemic features of the disease (19) (Table 34.2). Genetic screening can be adjunctive to clinical evaluation, in cases with suspected MFS or where other family members carry an identified causal mutation. However, FBN1 mutations are not specific to MFS and can be found in a wide range of phenotypes including mitral valve, aorta, skeleton, and skin (MASS) syndrome; familial mitral valve prolapse; and familial ectopia lentis (16). Mutations in TGFBR2 can be found in up to 21% of MFS patients who are FBN1 negative (20,21). Conversely, the above type of the disorder, termed as MFS type 2, has a phenotype overlapping with that of Loeys-Dietz syndrome, a dominant disease that is similar to MFS, but patients have bifid uvula and widely spaced eyes, and some have cleft palate (5). The presence of ectopia lentis, which is absent in the latter, can be useful in the differential diagnosis between the two syndromes (22).

The most characteristic and troublesome features of MFS involve the cardiovascular system and include TAA formation, aortic regurgitation owing to an enlarged aortic root, and mitral valve prolapse (5). Aortic enlargement is typically located at the level of sinuses of Valsalva and may eventually extend to the sinotubular junction and proximal ascending aorta (Fig. 34.1B) (23). Approximately 35% of MFS patients develop aortic root dilation by the age of 5 years and 68% by the age of 19 years (24). Dilation is progressive although its rate is unpredictable and can vary even in the same patient (25). The incidence of serious cardiovascular complications, including aortic dissection or rupture, has been estimated to be around 4.3% in childhood with a rise to approximately 20% in adolescence (26). Aortic regurgitation may develop in 15% to 44% of MFS patients during childhood and adolescence, and has been strongly associated with acute cardiovascular events (27). Additional predictors of aortic complications include younger age at presentation and a family history of severe aortic disease (26). Patients diagnosed with MFS during childhood have significantly fewer adverse cardiac events compared to those diagnosed during adulthood, highlighting the importance of early identification of the disease (28).

Following diagnosis of MFS, an echocardiogram is recommended at 6-month intervals to assess the progression of aortic disease. If measurements remain stable, echocardiographic follow-up can be performed on an annual basis (5). However, those guidelines refer to adult patients, and it has been suggested that younger patients should be monitored every 6 months, particularly during accelerated growth phases (29). Children who do not meet the full diagnostic criteria of the disease should be screened at least every 5 years until they reach adulthood (29). Baseline echocardiographic imaging requires diameter measurement at the level of the sinuses of Valsalva, which is the typical affected aortic segment in MFS. Of note, aortic root diameters should be indexed to age and body surface area (30). It has been suggested that an adjusted nomogram with higher upper limits should be used for the diagnosis of aortic dilation in children with MFS, as they tend to be taller compared to their peers (31). In the instance of poor echocardiographic windows, magnetic resonance imaging (MRI) or computed tomography (CT) angiograms should be performed (Fig. 34.2A). Importantly, both of the above modalities measure external diameter, which is

Different patterns of aortopathy in CHD

Figure 34.1. Different patterns of aortopathy seen in congenital heart disease (CHD). **A:** Anterior view of a normal aortic root, ascending aorta, and aortic arch. **B:** Typical location of aortic dilation at the level of sinuses of Valsalva in patients with Marfan syndrome. **C:** Asymmetric pattern of ascending aortic dilation encountered in stenotic bicuspid aortic valve (BAV) disease. **D:** Uniform dilation of aortic root and ascending aorta following repair of Tetralogy of Fallot (TOF).

0.2 to 0.4 cm higher compared to the internal diameter measured by echocardiography (5). Precise measurements are difficult due to movement of the ascending aorta in three planes and the difficulty of obtaining a true cross-sectional diameter of the aorta. Therefore, recommendations in asymptomatic patients based on diameter values in guidelines should be made with caution.

Routine CT or MRI imaging of the entire thoracic aorta is recommended in patients who present with descending aortic dilation, with type B aortic dissection, or following ascending aortic aneurysm repair (32). The vast majority of MFS patients present with dilation of the ascending aorta or type A dissection (5). However, in a smaller subset of patients, the disease initially involves the distal thoracic aorta with reported poor outcomes in cases of acute type B aortic dissection (33). Moreover, up to 52.6% of MFS patients who underwent initial repair of the ascending aorta had subsequent vascular procedures involving portions of their descending thoracic aortas (34), prompting comprehensive imaging follow-up. Increased regional wall stiffness assessed by MRI may be an additional marker for extensive screening, as it has been shown to be a predictor of progressive descending aortic dilation in MFS (35).

Figure 34.2. Magnetic resonance images of different types of aortic dilation. **A:** Still frame from steady-state free precession image showing the “pear-shaped” aortic dilation seen in Marfan syndrome. A jet of mild aortic regurgitation is seen. **B:** Jet lesion directed to the anterior–lateral portion of the ascending aorta in a stenotic bicuspid aortic valve with asymmetrical dilation of the vessel wall at the same level. **C:** Dilation of the aortic root extending to the sinotubular junction and proximal ascending aorta in a patient with repaired Tetralogy of Fallot.

Therapy

Both medical and surgical treatments have substantially increased life expectancy in MFS, extending it up to 70 years compared to 40 years in the 1970s (34). Conservative treatment consists of use of β -blockers and exercise limitation, with an aim to reduce arterial stress in MFS. Beta-blockade may be initiated at the time of diagnosis or in the presence of significant aortic dilation (32). Dosage must be closely monitored during accelerated growth phases and adjusted in case of adverse effects, such as asthma aggravation. If not well tolerated, medical treatment can be substituted with a calcium channel blocker. A protective effect of both agents has been reported on aortic growth rate in children and adolescents with MFS (36). Recently, in a pilot study including 18 children with MFS, the use of angiotensin II–receptor blockers (ARBs) significantly slowed the rate of progressive aortic root dilation (37). However, these data are preliminary, and the efficacy of ARB therapy in MFS is being investigated by two ongoing prospective randomized trials: one in the United States, coordinated by the Pediatric Heart Network of the National Heart Lung and Blood Institute (NHLBI), and the other in Europe, run by the Clinical Trials and Evaluation Unit (CTEU) of the Royal Brompton and Harefield National Health Service (NHS) Foundation Trust (38,39). Despite long-term treatment, major cardiovascular complications may still develop (36). Therefore, pharmacologic therapy can be used to delay surgical treatment in affected children, but the need for close follow-up is fundamental. Avoidance of maximal and isometric exertion is also recommended, although exercise restrictions may not always be applicable in younger children. An American Heart Association consensus document published in 2004 offers recommendations for physical activity in young patients with genetic cardiovascular diseases, including MFS (40).

Surgery for aortic root aneurysm in children with MFS has been reported to be safe with good long-term results (41). If the aortic valve is affected, a composite replacement of the valve and ascending aorta is performed. In cases with no substantial aortic valve disease, valve-sparing techniques can be applied, including remodeling of the aortic root or reimplantation of the aortic valve (Fig. 34.3). Creation of neo-aortic sinuses in the reimplantation technique is thought to enhance the durability of repair in MFS (42). Current recommendations for elective aortic root surgery in adults with MFS are based on the positive correlation between aortic diameters and risk of dissection. Nonetheless, there is a lack of similar data in children owing to the rarity of aortic complications in this age group. Due to the absence of general consensus in the pediatric population, most centers advise prophylactic surgery using the diameter criterion for adults (~ 50 mm) but also take into consideration the presence of accelerated aortic growth (>10 mm/year), development of aortic regurgitation, or need for mitral valve surgery (29). Following aortic root surgery, close follow-up and continuation of medical therapy is necessary, since distal segments of the aorta may also be affected (32).

BICUSPID AORTIC VALVE

BAV is the commonest congenital cardiac malformation with a prevalence of 0.5% to 2% (44,45). The term BAV has been used to describe a broad spectrum of malformations, including “true” BAV, denoting the presence of two fully developed valve leaflets, and “functional” BAV, with presence of three leaflets, two of which have been fused together. The disease is a heritable condition with familial studies demonstrating the occurrence of a BAV in approximately 9% of first-degree relatives of affected individuals (46). In some instances, the pattern

Figure 34.3. A: Bentall procedure, composite graft replacement of the aortic valve and the ascending aorta. The aortic cusps and sinuses are excised completely. A valved conduit is sutured to the aortic annulus, and the coronary arteries are reimplanted into the graft. B: Aortic root replacement with remodeling of the aortic root. A tubular Dacron graft is used with the proximal end tailored to reconstruct the aortic sinuses. The coronary arteries are reimplanted into their respective neo-aortic sinuses. C: Aortic root replacement with reimplantation of the aortic valve. The aortic sinuses are excised leaving a rim of aortic tissue attached to the aortic annulus and around the coronary artery orifices. The aortic valve is reimplanted inside a tubular Dacron graft using two suture lines, one below and one above the aortic annulus. The coronary arteries are reimplanted into their respective aortic sinuses, and the graft is anastomosed to the distal ascending aorta. (Mulder BJ, Webb GD. Marfan syndrome: a cardiovascular perspective. In: Gatzoulis MA, Webb GD, Daubeney P, eds. *Diagnosis and Management of Adult Congenital Heart Disease*. 2nd ed. Philadelphia, PA: Elsevier, Ref. 43).

of inheritance is autosomal dominant with variable penetrance and a male/female ratio of 3:1 (46,47). Development of a bile-alet aortic valve predisposes to several complications, including valvular dysfunction and infective endocarditis (48–51). Moreover, BAV is associated with structural pathologies of the aortic wall, including coarctation of the aorta, dilation of the ascending aorta, and TAA formation (52,53). As a result, BAV is considered as a continuum of a disease process affecting the entire aortic root and ascending aorta (54). Despite the lower incidence of aortic dissection compared to MFS (5% vs. 40%),

BAV disease is overall responsible for a larger number of dissections due to its higher prevalence (47).

The pathogenesis of vessel wall remodeling leading to aortic dilation in patients with BAV remains unclear and may be related to mechanical responses to local hemodynamics or to intrinsic structural abnormalities of the aortic wall. The latter is supported by evidence of cystic medial necrosis in the aortic media of BAV patients (Fig. 34.4). Fedak et al. (7) have proposed a defect of FBN1 synthesis as the culprit lesion for aneurysm development, having observed a reduction of expression

Figure 34.4. Histologic abnormalities in the aortic wall of patients with congenital heart disease. Image (A) is from a normal aorta and (B) from a patient with a bicuspid aortic valve (BAV): (A) shows normal distribution of the elastic lamellae (purple), and (B) shows severe medial wall degeneration with elastic fiber fragmentation and accumulation of basophilic ground substance (pink). Both images are stained in elastic van Gieson. Magnification $\times 20$.

of this protein in the extracellular matrix of dilated aortas with BAVs (7). Deficiency of FBN1 leads to detachment of VSMCs from elastin and collagen and activation of MMPs, inducing accelerated apoptosis. Despite the similar underlying pathology with MFS, BAV patients are negative for mutations in the FBN1 gene (55). Notch homolog 1 (NOTCH1) gene may have a key role in BAV disease as mutations within this gene have been associated with both sporadic and familial BAV and TAA as well as increased calcium deposition on the aortic valve (56). The NOTCH1 gene encodes a transmembrane protein activating a signaling pathway in cardiac embryogenesis, involved in the development of the great vessels and the aortic and pulmonary valves (56). Mutations in the ACTA-2 gene, encoding VSMC α -actin, have been associated with familial thoracic aortic aneurysm and dissection (TAAD) disease and concomitant BAV (57). Endothelial nitric oxide synthase (eNOs) is another candidate gene product, as murine studies have exhibited a strong association between eNOs deficiency and the development of BAV (58). Finally, an X-linkage has been hypothesized due to association of BAV with Turner syndrome (45XO) and the male predominance of the disease (54).

While structural abnormalities of the aortic wall have been identified, local hemodynamic factors may also be operative in TAA formation. In vitro experiments have shown that cultured human endothelial cells respond to different levels of wall shear stress (59). Morphologic variations in BAV carry different risks of aortic dilation, which could be related to their different hemodynamic effect: anteroposteriorly oriented BAVs are more likely to develop regurgitation, whereas right-left oriented BAVs are more prone to stenosis, resulting in different flow patterns in the aorta (60,61). Stenotic BAVs create a high-velocity jet, which imposes increased shear stress on the right anterolateral portion of the ascending aorta, whereas regurgitant BAVs increase wall tension, due to higher stroke volumes, and correlate with aortic root dilation (Fig. 34.2B) (54). The hemodynamic effect has been investigated in collected tissue specimens from BAV patients, exhibiting different patterns of stress-induced vascular remodeling in the convexity versus the concavity of the enlarged aorta (62).

Aortic dilation has been shown to be present in the early stages of life and progressive throughout childhood in BAV disease. In a pediatric population of 107 patients with normally functioning BAVs, aortic root diameters assessed by echocardiography were significantly larger in BAV compared to controls (63). However, the greatest discrepancy was noticed at the level of the ascending aorta, with a faster rate of annual growth in BAV patients than controls. In a different study, the rate of ascending aortic dilation was reported to increase even further when children with BAV reach adolescence (64). Reported risk factors for ascending aortic dilation in BAV include aortic valve morphology, severity of outflow gradient and aortic regurgitation, and systolic left ventricular outflow jet angles (65). Despite the above findings, the incidence of aortic dissection is rare in children with BAV and only reported in isolated cases of adolescent patients (65). In a cohort of 981 children with BAV followed up in a single center, the incidence of primary cardiac events was approximately threefold lower than in young adults and was largely related to aortic stenosis with no cases of aortic dissection (65). Of note, the above study was restricted to isolated BAV disease, whereas Turner syndrome and prior coarctation repair are identified risk factors of aortic dissection in the adult BAV population (66,67).

Diagnosis

In view of the silent nature of aortic enlargement and the high mortality rates of aortic dissection, annual imaging has been recommended for BAV patients until the rate of progressive

enlargement has been established (1). In contrast with MFS, the location of maximal dilation is more distal and therefore, echocardiographic imaging may not provide complete assessment of aortopathy in BAV (Fig. 34.1C) (1). Compared to CT, MRI has the advantages of simultaneous evaluation of aortic valve pathology and left ventricular dysfunction without exposure to radiation (5). Moreover, the elastic properties of the ascending aorta can be assessed and may be used analogously to MFS in risk stratification for progressive dilation (68). Of note, recent AHA recommendations include echocardiographic screening of first-degree relatives of patients with BAV, as affected members may have isolated thoracic aortic dilation or increased aortic stiffness in the absence of BAV (5,69). Those findings suggest that BAV and TAA may share a common genetic background, as variable expressions of the same disease.

Therapy

Prophylactic β -blockade in BAV disease is based on consensus opinion and is recommended in patients with aortic dilation (>40 mm) without significant aortic regurgitation (70). Extrapolation of data on pharmacologic therapy in MFS cannot be made, due to the lack of clinical trials in BAV patients (54). Timing of surgical treatment in young patients with a BAV and dilated ascending aorta remains a challenge. Similar to children with MFS, diameter measurements cannot be associated with the risk of aortic dissection due to the rarity of such events in this age group. Therefore, the traditional threshold of 50 mm for aortic repair is used along with aortic growth rate exceeding 10 mm/year, and an aortic diameter of more than 45 mm for aortic valve surgery (71). Valve-sparing procedures are favorable in children with an aortic annulus >18 mm. The presence of a bileaflet aortic valve is not necessarily a contraindication to a valve-sparing operation unless there is significant valve regurgitation, leaflet distortion, or calcification (71). Use of a composite valve graft is preferable in cases of acute aortic dissection and abnormal aortic valve leaflets. Homografts can be used as an alternative in children with an annulus of <18 mm. However, their durability is limited leading to a reoperation rate of approximately 40% in several pediatric series (41,72–74). Finally, pulmonary valve autotransplantation (Ross procedure) remains a source of controversy in young patients with BAV who need an aortic valve replacement. Despite the satisfactory results of the procedure, durability limitations have been reported by the end of the first postoperative decade in younger patients (75). Pulmonary autograft dilation may occur following the Ross procedure with described intrinsic histologic abnormalities of the pulmonary root similar to those of the aorta in BAV disease (76). Predictors of autograft failure in children include the presence of preoperative aortic regurgitation and aortic root dilation (75).

TETRALOGY OF FALLOT

TOF is the most frequently encountered cyanotic heart lesion accounting for nearly 10% of all congenital heart defects (77). Approximately 7% of affected individuals have a deletion on chromosome 22q11 with important implications in terms of genetic counseling and family screening, due to the associated 50% risk of transmission (78). Aortic root dilation is a known feature of unrepaired TOF and has been attributed to increased aortic blood flow due to right to left shunting (79). However, progressive dilation also occurs in 15% to 48% of TOF patients following reparative surgery (79,80). The overall survival in repaired TOF has increased dramatically, with a reported 85% survival rate over a 36-year follow-up (81).

Excessive development of aortic enlargement is one of the contributing factors to late morbidity in this patient cohort (82). Aortic root dilation may lead to aortic regurgitation due to incomplete leaflet coaptation, necessitating aortic valve replacement (83). Moreover, aortic enlargement imposes the risk of aortic dissection and rupture in patients with TOF (83–85).

Aortic wall pathology in TOF has been postulated to occur due to the influence of increased blood flow from both ventricles to the overriding aorta, prior to anatomical repair (79). This is further supported by the fact that dilation is greatest in patients with pulmonary atresia, the extreme end of the morphologic spectrum of TOF, where volume load through the aorta is maximal (79). However, intrinsic histologic abnormalities are also present in the aortic media of TOF patients, similar to the processes of cystic medial necrosis described in MFS and BAV disease (6,82). Those structural changes can be seen not only in the aorta of adult TOF patients, where the hemodynamic component has been removed, but also in infants and neonates, only a few days old (82). It remains unknown whether hemodynamic stress, even present before birth, is the causal mechanism for the structural changes in the aorta. Even if that is the case, progressive aortic dilation only takes place in a subset of TOF patients, where a genetic component could be equally operative. A recent study reported the vasoprotective role of an MMP-9 genetic polymorphism in TOF patients, which was associated with lower aortic stiffness and smaller z score of the aortic sinotubular junction (86).

Dilated aortic segments in TOF patients include the aortic root and ascending aorta (Fig. 34.1D) (82). Among unoperated patients, those with TOF and pulmonary atresia have greater aortic enlargement (87,88). Aortic root dilation has been described in children following TOF repair with a prevalence of 88%, 87%, 61%, and 63% at the annulus, sinus of Valsalva, sinotubular junction, and ascending aorta, respectively (89). A different study reported similar findings with increased diameters in the first 3 to 6 months after palliative shunt surgery (90). Interestingly, root dimensions “normalized” by 7 years of age in TOF patients who had undergone repair in infancy, whereas aortic dilation persisted into adulthood in those repaired after 1 year of age (90). Identified risk factors for progressive aortic dilation in repaired TOF include male sex, longer time interval from palliation to repair, and presence of pulmonary atresia and right aortic arch (79). Aortic wall stiffness may be an additional risk stratifier, as it was found to be increased in both children and adults with repaired TOF and was closely associated with aortic root dilation (91).

In case of progressive dilation, imaging of the aorta is recommended on an annual basis (Fig. 34.2C) (1). Similar to BAV disease, there is currently no consensus on prophylactic β -blocker treatment in TOF patients with aortic root dilation. Moreover, no guidelines for timing of aortic root surgery have been reported. Despite the increased recognition of aortic pathology in this patient cohort, aortic dissection has only been reported in a few isolated cases with an aortic diameter of ≥ 55 mm with additional risk factors (84,85). Therefore, it may be that aortic root replacement should be considered in TOF patients when aortic diameter exceeds 55 mm, especially when there is an indication for pulmonary valve implantation (79). Additional soft indications may include the development of aortic regurgitation with a root diameter of more than 50 mm, similar to patients with MFS (79). However, these are all arbitrary and clearly merit further investigation.

COARCTATION OF THE AORTA

Coarctation of the aorta has an incidence of 0.3 to 0.4 in 1,000 live births, accounting for 5% to 7% of all CHD (92,93). More than 50% of affected patients have a BAV with

similar underlying structural abnormalities in the aortic media (6). Aneurysm formation is a known clinical feature of the disease and may occur at the site of previous surgical repair or in the proximal aorta (94). Natural history studies report dissection of the aorta as the cause of death in 19% of patients with coarctation, reaching 50% in the presence of a concomitant bileaflet aortic valve (95). The disease is associated with significant cardiovascular morbidity, even following surgical repair, with survival rates of 72% at 30 years (96). The commonest cause of late death is coronary artery disease followed by sudden death, heart failure, cerebrovascular accidents, and ruptured aortic aneurysm (96).

Structural abnormalities of the aortic media in coarctation patients have been reported within 24 hours after birth, implying an intrinsic underlying cause (97). Moreover, medial wall abnormalities were identical at sites subjected to high and low pressure (proximal and distal ends of the coarctation site), eliminating the influence of hemodynamics in the described pathology (6). Nevertheless, it has been hypothesized that hemodynamics in the form of systemic hypertension in patients with coarctation and BAV may trigger apoptotic mechanisms in the latter, due to the higher incidence of ascending aortic dissection when the two entities coexist (95). Interestingly, both BAV and coarctation have a known male predominance as well as an association with Turner syndrome, leading to the hypothesis that a common genetic substrate may be located on the X chromosome (95). Finally, approximately 10% of patients with coarctation and 10% of patients with isolated BAV have concurrent intracranial aneurysms (98). Cardiac structures derived from neural crest cells include the outflow tract of the heart and the aortic arch system, as well as the cervicocephalic arteries. Maldevelopment of the neural crest may lead to vascular fragility, supporting the concept that BAV and coarctation may belong to a spectrum of diffuse aortopathy (98,99).

Despite successful surgical repair of coarctation, approximately 9% of patients develop aortic aneurysms late after the operation, with potential aortic rupture and death (100). Development of aneurysm at the site of surgical repair is associated with the patch graft technique and repair of coarctation before the age of 14 (100). Predictors of ascending aortic aneurysm formation include the coexistence of a BAV and advanced age, with a 1.4 risk ratio per decade of age at follow-up (94). As such, coarctation is considered to be a lifelong disease and requires close surveillance of the aortic sequelae, especially in patients with concomitant BAV. Imaging follow-up of both the ascending and descending thoracic aorta is recommended in coarctation patients, irrespective of previous repair, for early detection of aortic wall complications (94,101). Prophylactic treatment with β -blockade as well as appropriate timing of surgical intervention on the dilated ascending aorta in this patient cohort remain uncertain. Most centers use the criteria applied for aortic surgery in MFS, whereas novel surgical techniques may be required in patients with coarctation and a BAV (95,102).

TRANSPOSITION OF THE GREAT ARTERIES

Complete TGA is the second most common cyanotic heart defect, accounting for 5% of all congenital heart defects (103). TGA has a prevalence of 20 to 30 in 100,000 live births, with a 2:1 male predominance (103). Arterial switch operation (ASO) has become the preferred technique for anatomic correction of TGA, offering the advantage of a systemic left ventricle over the Mustard procedure. However, ASO is not without late complications, including development of neo-aortic dysfunction, with dilatation of the proximal ascending aorta resulting in aortic regurgitation (104). At a median follow-up of

4.9 years following ASO, the incidence of neo-aortic regurgitation of all grades was 16% (104). Nonetheless, the cumulative incidence of grade 2 or higher regurgitation was 9% at 15 years, with pulmonary outflow obstruction reported as the main cause for reoperation. To date, no cases of neo-aortic dissection or rupture have been reported although, taking into consideration the relative young age of the ASO, the magnitude of aortic complications cannot be fully appreciated. In the largest published series of 1,200 infants who underwent ASO between 1982 and 1999 in a single center, only a substrate of 1,095 survivors is currently reaching adulthood (104).

Histologic abnormalities, similar to those seen in MFS and BAV, have been described in normal-sized ascending aortas of neonates with TGA undergoing arterial switch (6). These findings may imply an inherent structural weakness of the aortic wall in patients with TGA. Interestingly, aortic root pathology has also been described in this lesion following the Mustard procedure, but may be largely underestimated due to other serious complications of the technique, such as right ventricular dysfunction, arrhythmias, and sudden cardiac death (1). Despite the evidence of intrinsic abnormalities, hemodynamics may also have a causal role in aortic dilation in TGA. Sharper angulation of the aortic arch in patients with TGA has been associated with greater pulse wave reflection, dilation of the ascending aorta, and aortic regurgitation late after the ASO (105).

During echocardiographic assessment of TGA patients who had undergone ASO, neo-aortic root dilation, defined as a z-score ≥ 3 , was reported in 33.4% at a median follow-up of 5 years (106). Importantly, in the majority of patients with neo-aortic dilation, a stabilization of z-scores was observed during late follow-up, suggestive of absence of progressive dilation. Risk factors for neo-aortic dilation included previous pulmonary artery banding and older age at operation. Freedom from reoperation on the neo-aortic valve or root was 95% at 10 years. According to current recommendations, annual follow-up is suggested for TGA patients undergoing ASO with root intervention in the instance of severe neo-aortic root dilation (>55 mm) (103). Longer term follow-up will be available for ASO patients in the future and may further elucidate the mechanisms of neo-aortic dilation in this cohort.

OTHER LESIONS

Structural abnormalities of the aortic media have been documented in a wide range of congenital heart defects, including ventricular septal defect, truncus arteriosus, double outlet right ventricle, tricuspid atresia, and double aortic arch (6). These changes may be present as early as the neonatal period, raising the question of a common genetic substrate that is yet to be elucidated.

CONCLUSIONS

Increasing recognition of aortic complications in patients with CHD has led to a significant change in our perception of aortic enlargement from a model of "poststenotic dilation" to a co-existent intrinsic aortopathy. Despite the exponential research in this field during the last decade, there is a paucity of data in terms of available genetic screening and development of new therapies. Following the paradigm of FBN1 mutations in MFS, complete sequencing of the gene currently incurs a prohibitive cost, and no clear genotype-phenotype correlation exists. Similarly, despite our deeper understanding of the pathogenetic mechanisms implicated in aneurysm formation in MFS, β -blockers remain the mainstay of pharmacologic therapy.

However, recently recognized molecules promoting aneurysm formation are being targeted in animal models. Such examples include angiotensin receptor drugs, which reduce TGF β activity as well as doxycycline, which acts as an MMP inhibitor (29). Likewise, genetic sequencing is a useful tool for screening of first-degree relatives of patients who are positive for a mutation associated with aortic aneurysm formation, such as FBN1 and ACTA2 (5). Overall, the prognosis of patients with aortic root abnormalities and CHD has improved substantially over the past decades, mainly as a result of early diagnosis and timely intervention. As life expectancy of patients with CHD increases, so will our understanding of the pathogenetic mechanisms implicated in aortic disease.

David W. Brown ■ Tal Geva

Anomalies of the pulmonary veins vary widely in their anatomic spectrum and clinical presentation, course, and outcome. As with other types of congenital heart disease, advances in diagnosis, cardiovascular surgery in newborns and infants, and transcatheter therapy have heightened the importance of early recognition, accurate diagnosis, and better understanding of abnormalities of the pulmonary veins.

ANATOMY

Pulmonary venous anomalies may be categorized as anomalous connections, anomalous drainage with normal connections, stenotic connections, and abnormal numbers of pulmonary veins.

Anomalous Connections and Drainage

One or more of the pulmonary veins may connect anomalously to one or more of the systemic veins. The condition is termed totally anomalous pulmonary venous connection (TAPVC) if all the veins connect anomalously, and partially anomalous pulmonary venous connection (PAPVC) if one or more, but not all, of the veins connect anomalously.

The physiologic consequence of anomalous pulmonary venous connection is usually anomalous pulmonary venous drainage. It is also possible, however, to have normal pulmonary venous connections with abnormal drainage. Examples of this condition include a common atrium and malposition of the septum primum. Although the pulmonary veins in these anomalies connect normally (e.g., into the back wall of the atria between the right and left horns of the sinus venosus), either complete absence of the interatrial septum or malattachment of the septum primum can lead to anomalous drainage into the morphologic right atrium (RA). When some or all of the pulmonary veins drain anomalously into the RA or its tributaries without being abnormally connected, the terms partially anomalous pulmonary venous drainage (PAPVD) or totally anomalous pulmonary venous drainage (TAPVD) with normal pulmonary venous connections are used. Therefore, the terms pulmonary venous connections and pulmonary venous drainage should not be used synonymously.

We dedicate this chapter to the late Dr. Stella Van Praagh who was a coauthor in the sixth and seventh editions of this textbook.

Stenotic Connections

Stenosis in one or more of the pulmonary veins or in the common pulmonary vein may occur. Veins with normal connections may exhibit stenoses, varying from stenosis of one or more of the individual pulmonary veins to cor triatriatum. These produce obstruction to pulmonary venous return to the left atrium (LA). Anomalous connected veins may be stenosed, resulting in obstruction to pulmonary venous return to the RA. The physiologic feature common to these stenotic connections is obstruction of egress of pulmonary venous blood.

Abnormal Numbers of Pulmonary Veins

Normally, there are two right and two left pulmonary veins. The most common variation is the presence of a single pulmonary vein on either the right or left side, with a prevalence of about 24% in anatomic studies (1). Rarely, all pulmonary veins enter a common pulmonary vein that drains into the LA. A single left pulmonary vein was found more frequently than a single right (1). A single common pulmonary vein, usually without stenosis, occurs almost exclusively in cases of visceral heterotaxy with asplenia. It also is possible to have an increased number of normally connecting pulmonary veins. The prevalence of a third pulmonary vein on either the right or left side is 1.6% to 2% (1). A fourth or even a fifth vein infrequently is present. An abnormal number of pulmonary veins imposes no physiologic handicap.

EMBRYOLOGY

A classification of pulmonary venous anomalies based on embryologic principles introduces a unifying concept to the consideration of these anatomically and physiologically diverse conditions. Review of the embryologic development of the pulmonary venous system is a prerequisite.

In the human embryo, the primordia of the lungs, larynx, and tracheobronchial tree are derived by a division of the foregut. In their early stages of development, the lungs are enmeshed by the vascular plexus of the foregut, the splanchnic plexus. As pulmonary differentiation progresses, part of the splanchnic plexus forms the pulmonary vascular bed. At this stage, there is no direct connection to the heart. Instead, the pulmonary vascular bed shares the routes of drainage of the splanchnic plexus (i.e., umbilicovitelline and cardinal systems

Figure 35.1. Development of the pulmonary veins. **A:** At 27 to 29 days of gestation, the primordial lung buds are enmeshed by the vascular plexus of the foregut (the splanchnic plexus). At this stage, there is no direct connection to the heart. Instead, there are multiple connections to the umbilico-vitelline and cardinal venous systems. A small evagination can be seen in the posterior wall of the left atrium to the left of the developing septum secundum. **B:** By the end of the first month of gestation, the common pulmonary vein establishes a connection between the pulmonary venous plexus and the sinoatrial portion of the heart. At this time, the connections between the pulmonary venous plexus and the splanchnic venous plexus are still patent. **C:** Next, the connections between the pulmonary venous plexus and the splanchnic venous plexus involute. **D:** The common pulmonary vein (CPV) incorporates into the left atrium, so that the individual pulmonary veins connect separately and directly to the left atrium. LA, left atrium; LCCV, left common cardinal vein; LLB, left lung bud; RA, right atrium; RCCV, right common cardinal vein; RLB, right lung bud; UV, umbilical vein. (Adapted from Lucas RV Jr, Anderson RC, Amplatz K, et al. Congenital causes of pulmonary venous obstruction. *Pediatr Clin North Am* 1963;10:781–836.)

of veins) (Fig. 35.1A). Subsequently, the intraparenchymal pulmonary veins connect with the LA by establishing a connection with the common pulmonary vein, which evaginates from the LA (2).

No unanimous opinion about the site of development of the common pulmonary vein has been attained. Some investigators believe the common pulmonary vein originates from an evagination in the sinoatrial region of the heart (3). Others believe that the common pulmonary vein starts from a confluence of vessels from the pulmonary plexus (1). According to a third opinion, the beginning of the common pulmonary vein occurs by the confluence of capillaries that grow into the mesocardium, located between the lung buds and the heart. Nevertheless, it is generally accepted that, by the end of the first month of gestation, the common pulmonary vein can be identified as a vessel draining the pulmonary plexus and entering the sinoatrial portion of the heart. The site of entry is cephalad to the junction of the left and right horns of the sinus venosus and to the left of the developing septum primum (Fig. 35.1B) (3,4).

When the direct connection to the heart is established, the initial communications between the pulmonary portion of the

splanchnic plexus and the cardinal and umbilicovitelline systems are, for the most part, obliterated. The pulmonary vascular bed then drains via four individual major pulmonary veins into the common pulmonary vein, which in turn empties into the LA (Fig. 35.1C). The common pulmonary vein is a transient anatomic structure. By a process of differential growth, it becomes incorporated into the LA, resulting in the ultimate anatomic arrangement wherein the four individual pulmonary veins connect separately and directly to the LA (Fig. 35.1D).

Imperfect development of the common pulmonary vein provides embryologic basis for most anomalies of the pulmonary veins. The following aberrations of development of the common pulmonary vein explain these anomalies and are used as a means of classifying them (Table 35.1).

Early Atresia of the Common Pulmonary Vein while Pulmonary–Systemic Venous Connections are Still Present

If the common pulmonary vein fails to develop or becomes atretic early in its development, collateral channels for

TABLE 35.1 Embryologic Classification of Pulmonary Venous Anomalies

- I. Normal absorption of the common pulmonary vein associated with defects that result in abnormal pulmonary venous drainage
 - A. Sinus venosus defect
 - B. Malposition of septum primum
- II. Atresia of the common pulmonary vein (early) while pulmonary-to-systemic venous connections are still present
 - A. Partially anomalous pulmonary venous connection
 - B. Totally anomalous pulmonary venous connection

- IV. Stenosis of the common pulmonary vein
 - A. Cor triatriatum
- V. Abnormal absorption of the common pulmonary vein into the LA
 - A. Stenosis of the individual pulmonary veins
 - B. Abnormal number of pulmonary veins

pulmonary venous drainage are available in the form of primitive connections between the splanchnic plexus and the cardinal or umbilicovitelline systems of veins (Fig. 35.2). Any one of these collateral channels may persist and enlarge, resulting in TAPVC. If only the right or left portion of the common pulmonary vein becomes atretic, persistence of the pulmonary venous–systemic venous connections of that side provides the etiologic basis for PAPVC (5) (Fig. 35.2).

Late Atresia of the Common Pulmonary Vein after Pulmonary–Systemic Connections Are Obliterated

When atresia of the common pulmonary vein occurs late, the collateral venous channels already are obliterated. The resulting anomaly has been termed atresia of the common pulmonary vein. The individual pulmonary veins empty into a blind cul-de-sac that has no direct connection to the LA or to the systemic venous systems (Fig. 35.3A).

Stenosis of the Common Pulmonary Vein

Cor triatriatum is the result of stenosis of the common pulmonary vein (Fig. 35.3B and 35.4). In the usual case, the stenosis occurs late, after collateral venous connections have been lost, or else the severity of the obstruction produced by

Figure 35.2. Embryologic basis of partially and totally anomalous pulmonary venous connections. **A:** Partially anomalous pulmonary venous connection results from failure to establish a normal connection between one or more of the pulmonary veins with the common pulmonary vein (CPV) before the connections with the splanchnic venous system have regressed. **B:** Totally anomalous pulmonary venous connection results from failure to establish a normal connection between the pulmonary venous plexus and the common pulmonary vein before the connections with splanchnic venous system have regressed. HVC, horizontal pulmonary venous confluence; LCCV, left common cardinal vein; LIV, left innominate vein; LLB, left lung bud; RCCV, right common cardinal vein; RLB, right lung bud; VV, vertical vein. (From Edwards JE. Symposium on anomalous pulmonary venous connection (drainage): pathologic and developmental considerations in anomalous pulmonary venous connection. *Proc Staff Meetings Mayo Clin* 1953;28:441–452, with permission.)

Figure 35.3. Embryologic basis of atresia of the common pulmonary vein and cor triatriatum. **A:** The common pulmonary vein (CPV) has established a connection with the left atrium, and the primitive venous connections have regressed (**center panel**). Normally, the connection between the common pulmonary vein and the left atrium enlarges. If the normal connection between the common pulmonary vein and the left atrium fails, the pulmonary veins drain into a blind cul-de-sac without a significant alternative egress for pulmonary venous blood (atresia of the common pulmonary vein). **B:** The connection between the common pulmonary vein and the left atrium is stenotic, and the common pulmonary vein dilates (cor triatriatum). LCCV, left common cardinal vein; LIV, left innominate vein; LLB, left lung bud; RCCV, right common cardinal vein; RIV, right innominate vein; RLB, right lung bud.

cor triatriatum is insufficient to stimulate maintenance of the primitive routes of venous drainage. Occasionally, however, cor triatriatum may be associated with anomalous pulmonary venous connection, implying that in such cases, the obstruction was early enough and sufficient to favor persistence of one of the primitive drainage channels such as a levoatriocardinal vein.

Anomalous Incorporation of the Common Pulmonary Vein into the Left Atrium

Abnormal numbers of pulmonary veins are the result of imperfect incorporation of the common pulmonary vein into the LA. Incomplete absorption of the common pulmonary vein results in fewer than the normal number of pulmonary veins (1). Rarely, in the mature heart, a common pulmonary vein draining both lungs empties into the LA. More commonly, a single pulmonary vein drains one lung. If more than the usual

absorption takes place, there will be an increased number of pulmonary veins.

Stenosis in individual pulmonary veins at their junction with the LA may or may not be a consequence of abnormal incorporation of the common pulmonary vein. One or more of the veins may be affected. Trauma, inflammation, proliferative disorder, or other yet unidentified mechanism(s) may cause stenosis of the individual pulmonary veins.

Early Atresia of the Common Pulmonary Vein while Pulmonary–Systemic Venous Connections Are Still Present

Partially Anomalous Pulmonary Venous Connection

PAPVC is the congenital anomaly in which one or more, but not all, of the pulmonary veins are connected to a systemic vein. Winslow is credited with the first description of

Figure 35.4. Cor triatriatum sinister. Echocardiogram in the apical four-chamber view showing “classic” cor triatriatum sinister. The cor triatriatum membrane (arrow) separates the pulmonary venous confluence (PVC) from the low-pressure left atrial (LA) chamber, which includes the left atrial appendage. The only egress for pulmonary venous blood is through the membrane orifice. LV, left ventricle; RA, right atrium.

this anomaly in 1739 (6). By 1942, Brody (7) collected 65 cases from the literature. The advent of surgical correction of cardiac defects necessitated a more critical approach to diagnosis and resulted in the identification and description of hundreds of cases.

Hughes and Rumore (8) found PAPVC in 0.7% of a series of 280 anatomic dissections, and Healy (1) found 0.6% in a series of 801 anatomic dissections. Both figures are higher than those deduced from clinical studies, which implies that some patients with PAPVC are not recognized during life. The most common type of PAPVC is to the right superior vena cava (SVC), and the second most common is to the RA. In Healy's material, the incidence of those two sites together was 55% of the total number of 86 cases (1).

Our present understanding of the normal connections of the right pulmonary veins (RPV) in sinus venosus defects of the SVC or the right atrial type and in the cases of malposition of the septum primum explains why PAPVD occurs mostly into the right SVC and the RA (see sections on sinus venosus defects and malposition of the septum primum). In both anomalies, the common pulmonary vein developed normally and is incorporated normally into the LA. The abnormal drainage of the RPVs is due to defects other than abnormal development of the common pulmonary vein. Hence, the actual incidence of partial obliteration of the common pulmonary vein resulting in PAPVC is much lower than thought in the past.

If one considers the cases of sinus venosus defects with the RPVs draining into the SVC or RA, the cases of malposition of the septum primum with drainage of part or all the pulmonary veins into the RA, and cases with partially or totally anomalous pulmonary venous drainage but normal pulmonary venous connections, the incidence of PAPVC to a systemic vein is quite low.

Normal Absorption of the Common Pulmonary Vein with Partially or Totally Abnormal Pulmonary Venous Drainage and Normal Connection of the Pulmonary Veins

Sinus Venosus Defects

Sinus venosus defects allow an atrial-level or a supratratrial-level shunt, but they are not atrial septal defects (ASDs). Specifically, these defects do not involve the fossa ovale, septum primum, or septum secundum. They always are associated with drainage of some or all the RPVs into the right SVC or the RA, but the pulmonary veins are normally connected with the LA.

Van Praagh et al.'s study (9) of these defects based on post-mortem specimens and echocardiographic studies supports the following conclusions. The true defect is the deficiency of the common wall between the right SVC and the right upper pulmonary vein or the wall between the RA and the right upper and lower pulmonary veins (Fig. 35.5). The result of these deficiencies is the unroofing of the right upper pulmonary vein and its branches into the right SVC (sinus venosus defects of the SVC type) or the unroofing of the right upper and lower pulmonary veins into the RA (sinus venosus defect of the right atrial type) (9).

The interatrial communication is not a defect. It is the left atrial orifice of the unroofed pulmonary veins, as in cases of an unroofed coronary sinus (CS) where the interatrial communication is not a defect; rather, it represents the right atrial orifice of the CS.

Figure 35.5. Diagrammatic representation of sinus venosus defect. Unroofing of the common wall between the right superior vena cava (SVC) and the right upper pulmonary vein allows drainage of blood from the right upper pulmonary vein into the SVC and right atrium (RA). The interatrial communication (IAC) is not a defect. It is the native orifice of the right upper pulmonary vein (arrowheads), and it allows flow from the LA into the right atrium. Inset shows the normal course of the right upper pulmonary vein behind the superior vena cava. AS, atrial septum; IVC, inferior vena cava; MV, mitral valve; RPA, right pulmonary artery; S1°, septum primum; S2°, septum secundum; TV, tricuspid valve.

When the interatrial communication in sinus venosus defects is viewed from the LA, it is located posterosuperiorly to the upper border of septum primum, exactly in the position of the orifice of the RPVs. In the SVC type of sinus venosus defects, the true defect is much larger than

the interatrial communication (the orifice of the right upper pulmonary vein) and occupies all the area where the orifices of the branches of the right upper pulmonary vein are seen to enter the right SVC (Fig. 35.6A). In the right atrial type of sinus venosus defects, the interatrial communication

Figure 35.6. Sinus venosus defect. Echocardiogram (A,B) and MRI (C,D) of sinus venosus defect. **A:** Transthoracic right sternal border view in a patient with SVC-type sinus venosus defect. The deficiency in the wall between the right upper pulmonary vein (RUPV) and the SVC is the sinus venosus defect. The interatrial communication is the orifice of the right upper pulmonary vein (asterisk). **B:** Subcostal oblique view in a patient with inferior-type sinus venosus defect with color Doppler comparison. Note the absence of tissue (asterisk) between the right lower pulmonary vein (RLPV) and right atrium (RA), with flow directed into the right atrium (red flow) from both the RLPV and the LA through the RLPV's normally connecting orifice. **C:** Axial plane cine MRI image showing the defect (asterisk) in the tissue that separates the posterior wall of the SVC and the anterior wall of the right upper pulmonary vein (RPV). The arrow indicates the left atrial orifice of the right upper pulmonary vein, which serves as a communication between the LA and the SVC (Ao, aorta). **D:** Sagittal plane cine MRI: The arrows indicate the sinus venosus defect between the right upper pulmonary vein (RUPV) and the SVC. LA, left atrium; RA, right atrium; RPA, right pulmonary artery.

from the left atrial view is again in the position of the orifice of the RPVs. From the right atrial view, the missing partition between the RPVs and the RA can be imaged clearly by echocardiography (Fig. 35.6B). In both types of sinus venosus defects, the surgeon does not close the interatrial communication. Instead, the operation aims to restore the original function of the interatrial communication as the left atrial orifice of the RPVs (9), which can be accomplished by “reroofing” the pulmonary veins, that is, by patching the missing wall between the SVC and the pulmonary veins or between the RA and the pulmonary veins. The true nature of the interatrial communication, the left atrial orifice of the RPV(s), is thus restored.

Malposition of Septum Primum

Edwards (2) and Moller et al. (10) observed that, when the septum secundum is absent (usually in cases of visceral heterotaxy with polysplenia), septum primum may be displaced toward the anatomic LA (left sided or right sided, depending on the type of atrial situs). This displacement

of the upper border of the septum primum will result in the incorporation of some or even all the pulmonary veins into the morphologically RA. Although this malformation differs from sinus venosus defects, here also the normally connected pulmonary veins will drain into the RA. The two-dimensional (2-D) echocardiograms of such patients will show the change in the plane of the septum primum and the normal connection of the pulmonary veins in the back wall of the atrium (Fig. 35.7). The displaced septum primum may not reach the posterior wall of the LA. In such cases, there will be a small interatrial communication that is not an ASD or a patent foramen ovale; rather, it is a septum primum malposition defect. If the septum primum has some fenestrations (foramina secunda), multiple small interatrial communications will be present. Finally, in cases where septum primum fuses with the posterior left atrial wall, there is no interatrial communication. Supporting evidence for the conclusion that the pulmonary veins are connected normally to the atrial wall is that they are located between the right and left SVCs (when two SVCs are present). This is the normal location for the atrial con-

Figure 35.7. Malposition of septum primum.

A: Subcostal long-axis echocardiographic view showing leftwardly malattached septum primum (arrow), which results in anomalous drainage of the right pulmonary veins (RPV) into the right atrium (RA). The left pulmonary veins drain normally in this patient. **B:** Systolic frame of cine MRI in the axial plane in a 6-month-old infant with visceral heterotaxy and polysplenia showing leftward malposition of septum primum leading to drainage of the right pulmonary veins into the RA. Notice the dilated left-sided azygous vein (Az), which carries the blood from an interrupted inferior vena cava to the left superior vena cava (LSVC). DAo, descending aorta; LA, left atrium; RLPV, right lower pulmonary vein.

nection of the common pulmonary vein (i.e., between the two horns of the sinus venosus just above the CS). The absence of septum secundum makes it possible to visualize the attachments of septum primum from the right atrial side in heart specimens, a unique finding of this malformation. The echocardiographic appearance of the displaced mobile upper border of the septum primum helps to establish the diagnosis *in vivo*.

The essential anatomic elements that make possible the malposition of the septum primum toward the anatomic LA include absence of septum secundum and a well-developed septum primum. Those two elements often are present in patients with visceral heterotaxy and polysplenia. Patients with asplenia, however, seldom have a well-developed septum primum that could become malpositioned. Instead, they often exhibit TAPVC to a systemic vein above or below the diaphragm.

PARTIALLY ANOMALOUS PULMONARY VENOUS CONNECTIONS

Anatomy

PAPVCs exhibit a wide anatomic spectrum. Almost every conceivable connection between the pulmonary veins, on the one hand, and the various systemic venous tributaries, on the other hand, has been reported (Fig. 35.8). Left-sided pulmonary veins usually connect anomalously to derivatives of the left cardinal system (i.e., the CS and the left innominate vein [LIV]). Anomalous connections of the RPVs usually are to derivatives of the right cardinal system (i.e., the SVC or inferior vena cava [IVC]). The embryologic splanchnic plexus is a midline structure, thus explaining the developmental possibility for crossed drainage of left-sided pulmonary veins to derivatives of the right cardinal system and vice versa. Excluding the cases previously considered

PAPVC to the right SVC and to the RA (now considered under sinus venosus defect and malposition of the septum primum), the most common type of PAPVC is of the left pulmonary veins to the LIV. The second most common types are anomalous connections of pulmonary veins from the right lung to the IVC.

Right Pulmonary Veins to Superior Vena Cava

As outlined in the section on sinus venosus defects, the RPVs may drain into the right SVC or into the RA without being abnormally connected with them. The upper lobe drains by one large or two or three smaller veins into the SVC below the azygous vein. The multiple orifices indicate that the unroofing of the right upper pulmonary veins extends into their branches. The vein from the right lower lobe usually enters the LA. The lower part of the SVC, between the azygous vein and RA, is dilated. An interatrial communication (the left atrial orifice of the unroofed pulmonary veins) usually is present. Occasionally, a secundum ASD also is present. Rarely an ostium primum ASD also exists. When the orifice of the right upper pulmonary vein is atretic, the atrial septum is intact. Persistence of a left SVC is an occasional accompanying finding.

Anomalous connection of a single pulmonary vein to the right SVC as an isolated lesion or in combination with a sinus venosus defect is possible. The anomalously connected pulmonary vein in such a case originates from the right upper lobe and enters the right SVC either through the azygous vein or cranial to the insertion of the azygous vein to the SVC.

Gross examination of the heart reveals features common to all cases, regardless of the specific site of anomalous connection. These include mild to moderate dilation and hypertrophy of the RA and right ventricle and dilation of the pulmonary artery. The left-sided chambers are normal. Specific anatomic features vary according to the site of connection.

Figure 35.8. Partially anomalous pulmonary venous connection: variants. **A:** Anomalous connection of the two left pulmonary veins (LPVs) to the left innominate vein to the SVC; the right pulmonary veins (RPVs) connect normally to the left atrium. **B:** Anomalous connection of the left pulmonary veins to the CS. **C:** Anomalous connection of the right pulmonary veins to the inferior vena cava (IVC) to right atrium junction; in association with right lung hypoplasia this is termed “scimitar syndrome.” (From Brown DW. Pulmonary venous anomalies. In: Lai WW, Mertens LL, Cohen MS, et al., eds. *Echocardiography in Pediatric and Congenital Heart Disease: From Fetus to Adult*. 1st ed. United Kingdom: Wiley-Blackwell, 2009:119–142, with permission.)

Figure 35.9. Scimitar syndrome. **A:** Chest radiogram in the posteroanterior projection showing the scimitar sign (arrowheads). Note the rightward shift of the cardiac silhouette. The inset shows a Turkish sword called scimitar. **B:** Catheter angiogram with catheter advanced from IVC up the SV in the same patient. Note the connection with the IVC close to the right atrial junction (arrow). **C:** 3-D lung surface volume rendering derived from computed tomography imaging in the same patient as (A). Note the degree of right lung hypoplasia.

Right Pulmonary Veins to Inferior Vena Cava

All the RPVs or occasionally the veins draining the right middle and right lower lobes enter the IVC either just above or below the diaphragm (Fig. 35.9). The normal pulmonary venous pattern of the right lung is altered in this condition, resulting in a “fir tree” configuration. The atrial septum is usually intact. This malformation, termed the scimitar syndrome by Neill et al. (5), frequently is associated with other anomalies, including hypoplasia of the right lung, anomalies of the bronchial system, horseshoe lung, secondary dextrocardia, hypoplasia of the right pulmonary artery, anomalous arterial connection to the right lung from the aorta, and pulmonary sequestration (11). Neill et al. (5) considered this a more primitive anomaly compared with other instances of PAPVC and suggested that it represents an anomaly of development of the right lung.

Left Pulmonary Veins to Inferior Vena Cava

Rarely, some or all of the left pulmonary veins can drain into the IVC. Juraszek et al. observed a case in which all the left pulmonary veins connected to the IVC below the diaphragm in association with an ostium secundum defect (Fig. 35.10). There was no additional heart defect, and both lungs were normal (12). Others also have reported cases of left-sided scimitar syndrome (13,14).

Left Pulmonary Veins to Left Innominate Vein

The LIV is the usual site of anomalous connection of the left pulmonary veins (Fig. 35.10A). The veins from the left upper lobe or from the whole left lung connect to the LIV via a persistent early embryonic pathway, which, because of its orientation, has been termed a vertical vein. An interatrial communication in the form of a secundum ASD or a patent foramen ovale is common.

The connecting vein between the left pulmonary veins and the LIV also has been called a persistent left superior vena cava (LSVC). This term is incorrect both embryologically and anatomically. Embryologically, the vertical vein represents a persistent early embryonic connection between the

Figure 35.10. Partially anomalous pulmonary venous connection. Catheter angiogram showing PAPVC of the LPVs to the inferior vena cava. IVC, inferior vena cava; RA, right atrium; RHV, right hepatic vein.

splanchnic plexus of the lung buds and the cardinal veins. Anatomically, it is positioned more posteriorly than the LSVC, which is located immediately behind the left atrial appendage. An LSVC connects either with the CS or with the LA when the CS is unroofed. When an left pulmonary vein drains into the LSVC, the LSVC also should connect with the CS or with the LA. In a rare case (1), the left upper pulmonary vein (LUPV) joined the left superior intercostal vein, which in turn joined the LSVC. The confluence of those three veins entered the LIV. The proximal segment of the LSVC was atretic (ligament of Marshall) but present. To avoid inadvertent occlusion of pulmonary venous drainage, it is important that the differential diagnosis between a vertical vein and persistent LSVC be made before performance of any surgical or transcatheter intervention.

Other Sites of Partially Anomalous Pulmonary Venous Connection

Uncommon sites of PAPVC of the left pulmonary veins are to the CS (Fig. 35.8), IVC, right SVC, left subclavian vein, and azygous vein. In rare cases, veins of both lungs connect anomalously to systemic veins, while some of the pulmonary veins connect normally to the LA. Functionally, these patients resemble patients with TAPVC.

Physiology

The fundamental physiologic disturbance of PAPVC is similar to that in ASD, that is, increased pulmonary blood flow (PBF) as a consequence of recirculation of oxygenated blood through the lungs. The factors that determine the hemodynamic state include the number of anomalously connected veins, the cross-sectional area of the anomalously draining pulmonary vascular bed, the site of the anomalous connections, the presence or absence of an ASD, and the size of the ASD.

Partially Anomalous Pulmonary Venous Connection with Intact Atrial Septum

When the atrial septum is intact, factors that determine the proportion of blood that drains through the anomalously connected veins include the number of veins that are anomalously connected and the amount of lung tissue involved, the relative resistance of the vascular beds normally and anomalously connected, compliance of the respective atria into which the normally and anomalously connected veins empty, and the presence and degree of obstruction to pulmonary arterial blood flow.

When a single pulmonary vein is anomalously connected, the anomalously draining blood flow is about 20% to 25% of the total PBF (6). It is of such slight hemodynamic significance that the lesion is rarely recognized clinically. Hughes and Rumore (8) found neither dilation nor hypertrophy of the right heart in two patients with a single-lobe PAPVC who died at middle age of rheumatic heart disease. When all but one of the pulmonary veins drain anomalously, the anomalously draining blood approximates 80% of the PBF. The physiology and clinical presentation of these patients are comparable to those of the patient with TAPVC.

When the veins of one lung drain anomalously, the factors of relative pulmonary resistance and relative receiving chamber compliance modify the relative blood flows. In one study of patients with PAPVC of the RPVs to the IVC with intact atrial septum (scimitar syndrome), calculated PBF to the anomalously connected vein was 24% to 32% of the PBF (15). This low flow is related to abnormalities of the right lung parenchyma and the frequently associated anomalies of arterial supply that are seen in the scimitar syndrome

(17). On the other hand, when anomalous connection of one lung is the sole abnormality, the anomalously draining blood flow approximates 66% of the PBF as a result of the greater compliance of the RA, to which the anomalous veins drain, and the lesser compliance of the LA, the chamber receiving the normally draining blood. Thus, in patients in whom partially anomalous venous connection is the sole abnormality, the right atrial pressure is usually lower than left atrial pressure. As long as pulmonary vascular resistance remains equal in both lungs and there is no pulmonary arterial stenosis, blood flow is greater in the anomalously connected lung.

The lobe or lobes drained by the anomalously connecting pulmonary vein also affect the magnitude of the left-to-right shunt. In the upright position at rest, PBF is distributed preferentially to the middle and lower lobes. In supine position and during exercise, PBF is redistributed to the upper lobes. Hence, the magnitude of the left-to-right shunt in a patient with PAPVC from one of the upper lobes may vary according to body position and level of activity.

Partially Anomalous Pulmonary Venous Connection with Atrial Septal Defect

When the ASD is small, the hemodynamic state closely resembles that of PAPVC with an intact septum. On the other hand, a large ASD significantly influences the hemodynamic picture. It is pertinent to review briefly the physiology of uncomplicated ASD, in particular, the preferential shunting that occurs in this anomaly.

Using indicator-dye dilution techniques, Burchell et al. (16) evaluated the relative contribution of each lung to the left-to-right shunt in patients with ASD. The average ratio of pulmonary blood flow (PBF) to systemic blood flow (SBF) was 3.5:1. The proportion of blood from the right lung that was shunted left-to-right averaged 84%, whereas the proportion of blood from the left lung that was shunted averaged 54%. Thus, blood from both lungs drained anomalously, but the right lung contributed more than the left lung to left-to-right shunt. This preferential shunting from the right lung in ASD has been shown experimentally to result from the proximity of the right pulmonary venous orifices to the ASD.

When PAPVC and ASD coexist, the hemodynamic picture may be similar to that of uncomplicated ASD. The left-to-right shunt may be large. This shunt is the result of anomalous drainage of most of the blood from the anomalously connected lung and of anomalous drainage of half or more of the blood from the normally connected lung via the ASD (16).

A small right-to-left shunt from the SVC (both systemic venous blood and anomalously draining pulmonary venous blood) is usual in the presence of a sinus venosus defect. Likewise, a small right-to-left shunt from the IVC is commonly seen in a secundum ASD. Pulmonary vascular disease has been reported in older patients with uncomplicated PAPVC (17). Although pulmonary hypertension is thought to be rare, its prevalence is unknown.

Clinical Features

The anomalous connection of one pulmonary vein usually is not apparent clinically. If all but one of the veins connect anomalously (subtotal TAPVC), the clinical features mimic those of TAPVC. The following features occur when the veins of one lung connect anomalously. Symptoms are uncommon in childhood, but some dyspnea may occur on exertion. Cyanosis is unusual during childhood, even though a small right-to-left shunt may exist, depending on the location of the PAPVC.

The frequency of patients presenting with cyanosis increases during the third and fourth decades as a result of changes in the pulmonary vascular bed, pulmonary hypertension, and increasing right-to-left shunt.

The clinical presentation of patients with the scimitar syndrome varies widely. Dupuis et al. (18) reported on 25 infants with the scimitar syndrome, and Gao et al. (11) reviewed the data of 13 such patients. All but two patients presented with severe symptoms in early infancy. Pulmonary hypertension was common and was secondary to a combination of conditions, including arterial blood supply from the descending aorta, stenosis of the anomalously connecting RPVs, pulmonary parenchymal abnormalities, and associated obstructive anomalies of the left heart and aorta. Hypoplasia of the right lung with secondary dextrocardia was common. In contrast, in a study of 122 patients with scimitar syndrome who presented later in life (the adult form of scimitar syndrome), symptoms were rare, the left-to-right shunt was <50% in 100 of the 122 patients, the pulmonary artery pressure was normal in 94 and mildly elevated in 28 patients, and the clinical outcome was good in most of these patients (19).

In the presence of an associated ASD, the physical findings are identical to those noted in uncomplicated ASD. When the atrial septum is intact, splitting of the second sound is not marked, and there is normal variation of splitting with respiration. A pulmonary outflow murmur is usually present, and a diastolic tricuspid flow murmur may be present.

Associated Cardiac Defects and Syndromes

PAPVC or drainage has been associated with other congenital cardiac defects and syndromes. Most notably, patients with visceral heterotaxy and polysplenia have a high incidence of PAPVD secondary to malposition of the septum primum, and patients with asplenia have a high incidence of TAPVC. Recent reports described a significant incidence of PAPVC in association with Turner and Noonan syndromes. A prospective evaluation of 21 patients with Turner syndrome by Moore et al. (20) showed three cases of PAPVC with intact atrial septum (14.3%). Of these 21 patients, 12 had the 45 XO karyotype. PAPVC was seen only in this latter population (incidence of 25%) but did not occur in the nine patients who had Turner syndrome of the mosaic type. Additionally, van Wassenaer et al. (21) reported the association of PAPVC with intact atrial septum in three patients with Turner syndrome. Hence, the possibility of PAPVC should be considered in any patient with either Turner or Noonan syndrome.

A rare but clinically important association is that of anomalous pulmonary venous connections with tetralogy of Fallot. A review of 1,183 patients with tetralogy of Fallot (22) described seven patients with anomalous pulmonary venous connections (0.6%). PAPVC was present in four patients, whereas the other three patients had TAPVC.

Diagnostic Features

Electrocardiographic Features

The electrocardiographic (ECG) findings are comparable to those seen in uncomplicated ASD. The rR' pattern and the rSR' pattern are most commonly seen; the ECG is occasionally normal. Peaked P waves and right ventricular hypertrophy of the systolic overload pattern occur in older patients exhibiting pulmonary hypertension. A frontal P-wave axis of $\leq 15^\circ$ (inverted P wave in lead III) has been described with sinus venosus defect. The ECG is often normal in the patient with intact atrial septum.

Radiologic Features

The routine chest radiogram reflects the increased PBF and right ventricular dilation. Additionally, there may be distinctive features dependent on the site of anomalous connection.

The patient with anomalous connection of the RPVs to the IVC has a crescent-like shadow in the right lower lung field (Fig. 35.9B). This characteristic shadow prompted Neill et al. (5) to coin the term scimitar syndrome for this group of patients. Hypoplasia of the right lung (Fig. 35.9D) and chest, mesocardia or dextrocardia, and pulmonary parenchymal abnormalities also may be seen on the chest radiogram when drainage is into the IVC.

When the SVC is the site of the anomalous connection, dilation of the lower portion of the SVC is often recognized just above the right atrial contour or as a double density just inside the upper atrial border. When the anomalous connection is to the azygous vein, this structure is enlarged and can be recognized on the chest radiogram as a rounded bulge in the right superior mediastinum at the right cardiac border.

When the LIV is the site of connection of the left pulmonary veins, the chest radiogram shows a prominent supracardiac shadow composed of the vertical vein on the left, the innominate vein above, and the SVC at the right (Fig. 35.11). These structures are the same ones that account for the characteristic "snowman" appearance when there is a TAPVC to the innominate vein, but the enlargement is not as prominent.

Echocardiographic Features

The key to accurate echocardiographic diagnosis of PAPVC and PAPVD is detailed comprehensive imaging of all cardiovascular structures. The individual pulmonary veins should be examined in every patient, particularly at the time of the first echocardiographic evaluation. The size and course of the individual pulmonary veins must be determined both by 2-D

Figure 35.11. Supracardiac totally anomalous pulmonary venous connection. Chest radiogram in the posteroanterior projection in a patient with totally anomalous pulmonary venous connection to the innominate vein showing the typical "snowman" appearance of the mediastinum. The *solid arrow* points to the shadow of the ascending vertical vein. The *white arrow* points to the shadow of the dilated right superior vena cava. Note the cardiomegaly secondary to right heart volume overload and the congested right pulmonary veins.

imaging and by color Doppler flow mapping. The connection and drainage of the right upper and right lower and the left upper and left lower pulmonary veins with the LA should be demonstrated unequivocally. This can be achieved from the subcostal, apical, parasternal, and suprasternal notch windows. The subcostal window is ideal for evaluating the pulmonary veins in infants and young patients with good subcostal acoustic windows. The parasternal, subclavicular, and suprasternal windows are used in older patients. Transesophageal echocardiography is useful in patients with suboptimal transthoracic acoustic windows. Magnetic resonance imaging (MRI) is a preferred noninvasive alternative to transesophageal echocardiography (see later discussion). The presence of right ventricular volume overload, manifested as right ventricular enlargement with flattening of the ventricular septum during diastole, is a useful clue for the presence of a left-to-right shunt but is not specific for PAPVC. The finding of right ventricular volume overload in the absence of an ASD should prompt a careful search for PAPVC.

The echocardiographic diagnosis of PAPVC is based on the demonstration of a connection between one or more of the pulmonary veins with a systemic vein. Typically, the systemic vein distal to the connection of the pulmonary vein is dilated, reflecting the increased flow. Anomalous connection of pulmonary veins to the SVC is best imaged from the suprasternal notch or high parasternal long-axis of the SVC. Similarly, high parasternal short- and long-axis views allow visualization of the anomalous connection of the pulmonary veins to the LIV (Fig. 35.12). The diagnosis can be made from the subcostal window in infants and young children. Enlargement of the LIV and the SVC associated with evidence of increased flow by Doppler are clues to the diagnosis.

The anomalous pulmonary venous connection to the CS is best imaged by scanning the posterior left atrioventricular

(AV) groove from the subcostal, apical, and parasternal windows. The dilated CS in this condition should be distinguished from the more common persistent LSVC.

Imaging of the anomalous connection of one or more of the RPVs with the IVC establishes the diagnosis of scimitar syndrome. The subcostal window is most useful in this condition. The presence of mesocardia or dextrocardia in 70% of patients and a smaller-caliber right pulmonary artery compared with the left pulmonary artery are useful clues. Other findings include blunting of the right border of the LA when both RPVs do not connect with the LA and demonstration of aortopulmonary collaterals by color Doppler flow mapping.

Sinus venosus defect of the inferior type can be a challenging diagnosis to make by echocardiography, particularly in distinguishing this entity from a posteriorly located secundum ASD. Banka et al. (23) demonstrated in a group of 45 patients with inferior-type sinus venosus defect that the rate of accurate preoperative diagnosis was only 36% and that patients with incorrect diagnoses had worse technical outcome scores postoperatively compared with those with the correct preoperative diagnosis (23).

Magnetic Resonance Imaging

Cardiac MRI is suited ideally for evaluation of pulmonary venous anomalies (Fig. 35.13). The wide field of view, excellent spatial orientation, and its inherent three-dimensional (3-D) nature allow unambiguous delineation of the course, connections, and drainage of the pulmonary veins independent of body size and acoustic windows. Also, the ability to depict noncardiovascular structures such as lung parenchyma, airways, bones, and soft tissue offer an advantage over

Figure 35.12. Partially anomalous pulmonary venous connection. Echocardiogram from the high left parasternal window in the transverse plane with color Doppler imaging showing partially anomalous pulmonary venous connection of the left upper pulmonary vein (LPV) to the LIV. Note the prominent jet of red (antegrade) flow into the inferior aspect of the LIV. LSCV, left subclavian vein.

Figure 35.13. Partially anomalous pulmonary venous connection. Three-dimensional reconstruction of gadolinium-enhanced magnetic resonance angiogram with an anterior view showing partially anomalous pulmonary venous connection of the left upper pulmonary vein (LUPV) to the left innominate vein (LIV), which then drains into the SVC.

echocardiography and angiocardiology. Another advantage of MRI is its ability to measure the hemodynamic consequences of anomalous pulmonary venous connections and drainage, including the pulmonary-to-systemic flow ratio and right ventricular size and function.

The anatomy of the pulmonary veins can be evaluated by a series of T1-weighted spin echo images in the axial (transverse), coronal, or oblique planes. This sequence offers excellent spatial resolution but provides only one image in each location. The use of ECG-gated cine MRI sequence allows rapid acquisition of multiple contiguous cine MRI slabs that cover the chest. Cine steady-state free precession MRI clearly depicts the size, course, and drainage of the pulmonary veins and their relations to neighboring structures. Turbulent flow is seen clearly by this sequence. The advent of magnetic resonance angiography (MRA) added a powerful tool that allows fast 3-D imaging of cardiovascular structures (Figs. 35.13 and 35.14). Phase-contrast cine MRI allows quantification of

Figure 35.14. Scimitar syndrome. Three-dimensional reconstruction of gadolinium-enhanced magnetic resonance angiogram in a posterior view in a 20-year-old male with scimitar syndrome. Most of the pulmonary venous return from the right lung enters into the inferior vena cava through the scimitar vein (arrow), and a large collateral artery from the abdominal aorta enters the right lower lobe (asterisk). A small right upper pulmonary vein connects normally to the left atrium with a small intrapulmonary connection (not shown). At cardiac catheterization, the scimitar vein was occluded near its junction with the inferior vena cava, thus diverting the venous return from the entire right lung into the left atrium. The arterial collateral vessel was occluded as well. L, left; R, right.

blood flow through the pulmonary veins, determination of systemic and pulmonary flow ($Q_p:Q_s$), and flow to the left and right lungs. Experience with MRI and MRA in the evaluation of anomalous pulmonary venous connections indicates that it is superior to echocardiography and angiocardiology (24,25).

Cardiac Catheterization

Cardiac catheterization usually is not necessary for the diagnosis of PAPVC, its differentiation from secundum ASD, or estimation of the magnitude of the left-to-right shunt. Clinical features, echocardiography, and MRI provide sufficient anatomic and hemodynamic preoperative data. Cardiac catheterization is still useful in selected cases, especially if pulmonary hypertension is suspected. Interventional catheterization is indicated to occlude aortopulmonary collaterals in scimitar syndrome.

When cardiac catheterization is performed, frequent oximetry sampling usually allows identification of anomalous pulmonary venous connection to the CS, to the azygous vein, and to the SVC. Oximetry is usually of little value when the anomalous connection is to the IVC because blood flow through the right lung is diminished and also because of the contribution of highly oxygenated blood to the IVC by the renal veins. Inability to pass the catheter from the RA to the LA or a difference between the right atrial pressure and the pulmonary wedge pressure is suggestive of PAPVC with intact atrial septum.

Selective angiography is of limited value if the anomalously draining veins enter the RA or close to it. When the anomalous connections are to more peripheral vessels, however, angiography usually can define the site of anomalous connection, for example, PAPVC to the IVC, SVC, LIV, and azygous vein. Performing selective pulmonary arteriography and watching the levophase for pulmonary venous return may image the connections. If the anomalous connection is entered, direct injection of radiographic contrast dye will delineate the anatomy.

Differential Diagnosis

The distinction between ASD and PAPVC by clinical evaluation is difficult to make but is academic. The capabilities of today's noninvasive imaging techniques (echo and MRI) allow accurate preoperative diagnosis. Ostium primum ASD and single atrium also result in left-to-right shunt at the atrial level; these may be differentiated on the basis of their characteristic ECG pattern (i.e., counterclockwise frontal vector loop and left axis deviation). TAPVC presents a strikingly different clinical picture, with severe pulmonary congestion and cardiac failure, usually leading to death prior to 6 months of age if not treated. Cyanosis is an additional distinguishing feature.

Treatment

Medical Management

When heart failure occurs, either as a result of increased PBF or as a consequence of pulmonary vascular disease, the usual measures are indicated. When pulmonary parenchymal anomalies are associated, as in anomalous connection to the IVC, medical measures may be of temporary benefit. The only definitive therapy in PAPVC, however, is surgical correction.

Surgical Treatment

Surgical treatment of PAPVC is indicated when patients exhibit evidence of pulmonary overcirculation or respiratory insufficiency. Some of the surgical techniques are summarized briefly in the following sections.

MALPOSITION OF SEPTUM PRIMUM WITH PARTIALLY ANOMALOUS PULMONARY VENOUS DRAINAGE TO THE RA

Because many patients with malposition of septum primum and PAPVD draining to the RA have additional cardiovascular malformations, surgical treatment must be individualized. In general, patients may be divided into the following three groups:

1. Patients with atrioventricular concordance in whom a biventricular repair can be achieved. In these patients, the atrial septum is excised, and a new septum is constructed so that the systemic and pulmonary veins drain into their corresponding atria.
2. Patients with atrioventricular discordance and two well-developed ventricles. In these patients, the pulmonary veins are baffled into the systemic ventricle and the systemic veins and then drain into the pulmonary ventricle.
3. Patients in whom a biventricular repair cannot be achieved. In this group, the malposition of the septum primum is usually not relevant to the modified Fontan operation or to the bidirectional Glenn shunt (26).

SINUS VENOSUS DEFECT

Van Praagh et al. (27) described four surgical techniques, which have been used in 44 patients with superior-type sinus venosus defects:

1. Patch closure of the defect between the SVC and the RPVs baffling the right upper pulmonary vein to the LA through its native orifice.
2. In addition to the patch closure of the defect in the wall between the SVC and the RPVs, a second patch was used to enlarge the SVC (double patch technique).
3. This technique, described by J. Lewis and first performed by Warden et al. (28), involves division of the SVC and azygous vein superior to the entrance of the pulmonary veins. The cranial end of the SVC is sewn to an incision in the right atrial appendage. The cardiac end of the divided SVC is oversewn, and a patch diverts the right pulmonary venous blood into the LA through the interatrial communication.
4. Enlargement of the interatrial communication and baffling the RPVs to the LA via the enlarged interatrial communication are used for the inferior (right atrial) sinus venosus defects.

PAPVC TO INFERIOR VENA CAVA

Repair has been accomplished in the presence of an ASD by dividing the anomalously connecting vein at its IVC junction and anastomosing it to the LA (29). Repair then can be continued as in PAPVC to the RA. When the atrial septum is intact, as is usually the case, the anomalously connected vein is transplanted to the right atrial wall, and then an ASD is created and made contiguous to the anomalously connected vein by patching. A third technique is to baffle the anomalously connecting scimitar vein through the IVC and RA to the LA via a surgically created ASD. All of the above techniques carry a substantial risk of postoperative stenosis of the RPV.

PAPVC TO CORONARY SINUS

When this anomaly is present, it may be repaired using the technique described for repair of TAPVC to the CS.

PAPVC OF LEFT PULMONARY VEINS TO INNOMINATE VEIN

Kirklin (30) corrected this anomaly by anastomosing the common left pulmonary vein to the base of the amputated left atrial appendage.

Prognosis

Untreated

There is a paucity of information on which to base a prognosis in this defect. Studies based on anatomic material (8) indicate that patients with one pulmonary vein connected anomalously and with an intact septum have an excellent prognosis and rarely present with cardiorespiratory symptoms. It would be erroneous, however, to apply this excellent prognosis to patients who present with symptoms. The natural history in these patients appears comparable to that in uncomplicated ASD.

Postoperative Course

The impact of operative intervention of PAPVC depends in part on the state of the pulmonary vascular bed at the time of surgery. In patients with high PBF, symptoms are reduced dramatically, postoperative studies reflect a normal physiology, and a near-normal longevity may be assumed. These favorable results cannot be anticipated in the patient who has developed pulmonary vascular disease.

Long-term follow-up of repair of PAPVC has been reported in few series. Gustafson et al. (31) operated on 38 patients with sinus venosus defect. They had one early operative death in a 31-year-old patient with severe pulmonary hypertension. Symptomatic SVC obstruction occurred in one patient. Sick sinus syndrome was present in one patient. Of the surviving 30 patients, all remained well over a 1-year to 24-year period of follow-up. Van et al. (32) reported on the follow-up of PAPVC of the left pulmonary veins to left SVC, innominate vein, or CS in 13 patients. They reported no operative deaths, and one patient developed postpericardiotomy syndrome. Clinical follow-up of these patients 1.5 to 8 years after surgical repair demonstrated no evidence of pulmonary hypertension or pulmonary venous obstruction. A recent multicenter study of long-term outcomes after surgical treatment of scimitar syndrome from the European Congenital Heart Surgeons Association (33) found an early postoperative mortality of 5.9% in 68 patients and two late deaths resulting from severe pulmonary arterial hypertension. There was a relatively high incidence of residual scimitar drainage stenosis (freedom from scimitar vein stenosis was 85% at 13 years) that did not appear to vary by surgical approach (33). Sick sinus syndrome has been reported after repair of sinus venosus defect. Postoperative arrhythmias are infrequent with other forms of PAPVC.

The postoperative patient should be monitored periodically for development of pulmonary venous obstruction and for arrhythmias. The obstruction can result from occlusion of the anomalous pulmonary veins and can result in no blood flow to the affected lung. This can be detected by ventilation perfusion scintigraphy, echocardiography, MRI, or angiography. The pulmonary venous obstruction also can be secondary to stenosis of the SVC or IVC, which could be relieved with balloon angioplasty or placement of a stent.

TOTALLY ANOMALOUS PULMONARY VENOUS CONNECTION OR DRAINAGE

TAPVC defines the anomaly in which the pulmonary veins have no connection with the LA. Rather, the pulmonary veins connect directly to one of the systemic veins (TAPVC) or drain into the RA (TAPVD) (Fig. 35.15).

The frequency of TAPVC is difficult to define. In Abbott's (34) series of 1,000 cases of congenital heart disease, there

Figure 35.15. Totally anomalous pulmonary venous connection. **A: Supracardiac.** Both right (RPV) and left (LPV) pulmonary veins join a common pulmonary venous confluence behind the heart that drains via a vertical vein to the undersurface of the left innominate vein and thence to the right atrium. **B: Cardiac.** The pulmonary venous confluence connects to the coronary sinus (CS), and thence to the right atrium via the coronary sinus ostium. **C: Infradiaphragmatic.** The pulmonary venous confluence drains inferiorly via a vertical vein to the portal vein (PV) or hepatic veins (HVs) and thence to the right atrium. **D: Mixed Connections.** Left pulmonary veins drain to the LIV, and right pulmonary veins to the coronary sinus in this example. SV, splenic vein; SMV, superior mesenteric vein. (From Brown DW. Pulmonary venous anomalies. In: Lai, WW, Mertens LL, Cohen MS, et al., eds. *Echocardiography in Pediatric and Congenital Heart Disease: From Fetus to Adult*. United Kingdom: Wiley-Blackwell, 2009:119–142, with permission).

were 4 instances of TAPVC. Another study recorded 2% of 800 autopsied cases of congenital cardiac disease in the first year of life (35). There is a marked male preponderance in TAPVC to the portal vein (3.6:1) (36), whereas there appears to be no sex prevalence in the other sites of connection.

Genetics and Epidemiology

The mechanism of transmission of TAPVC has not been elucidated. The Baltimore-Washington Infant Study, however, showed a possible association with exposure to lead, paint or paint-stripping chemicals, and pesticides (35,37).

Although there is no known genetic pattern of transmission of TAPVC, a monogenic pattern of inheritance has been suggested from the number of reported family cases in the literature among siblings (38). Among the affected families, the common denominator was the anomalous pulmonary venous connection; the site of the anomalous venous connection was usually not concordant. TAPVC and TAPVD have been associated with a few syndromes, most notably asplenia, polysplenia, and cat's-eye syndrome.

Anatomy

Numerous classifications of TAPVC have been advanced. Craig et al. (39) divided TAPVC as follows: (a) anomalous connection at the supracardiac level, (b) anomalous connection at the cardiac level (to the CS), (c) anomalous connection at the infracardiac level, and (d) anomalous connection at two or more of the above levels (mixed type). This classification is the most commonly used approach to date. Burroughs and Edwards (40) suggested a classification with prognostic implications based on the length of the anomalous channel (i.e., long, intermediate, or short); however, the prognostic and physiologic implications suggested by these classifications are not always true. Smith et al. (41) provided an alternative classification for TAPVC: Supracardiac (without pulmonary venous obstruction) and infradiaphragmatic (with pulmonary venous obstruction).

Earlier in this chapter, TAPVD to the RA secondary to malposition of the septum primum was discussed. This kind of TAPVD usually is associated with visceral heterotaxy and additional heart defects (30).

The frequencies of the various sites of TAPVC or drainage are shown in Table 35.2. More than one-third of the cases had the anomalous connection to the LIV.

TABLE 35.2 Comparison of Anatomic Site of Connection of TAPVC and TAPVD in Three Autopsy Series

Site of Connection or Drainage	Burroughs and Edwards (40) (% , N = 113)	Lucas et al. (36) (% , N = 71)	Delisle et al. (42) (% , N = 93)
Left innominate vein	36	35	26
Coronary sinus	16	16	1
Right atrium	15	2	8
Right superior vena cava	11	12	15
Portal system	13	23	24
Multiple sites	7	10	5
Unknown or other	2	0	4

TAPVC, totally anomalous pulmonary venous connection; TAPVD, totally anomalous pulmonary venous drainage.

The presence of an interatrial communication is necessary to sustain life; therefore, an ASD or patent foramen ovale is considered part of the complex. Also, the young age of the patients makes the presence of a PDA usual, and this is not considered a complicating defect. A rare exception was a case of TAPVC to the CS with intact atrial septum, multiple VSDs, and a persistent LSV to the CS who survived to the age of 11 years (42).

Gross examination of the heart shows several features common to all cases, regardless of the site of the anomalous connection. These include dilation and hypertrophy of the right ventricle and RA and dilation of the pulmonary artery. The left ventricle is of normal size, and left ventricular volume measured in life is usually within the normal limits. Left atrial size

usually is diminished because it lacks the contribution of the common pulmonary vein. In addition to these findings, specific anatomic features vary as to the site of the anomalous connection as follows.

Connection to the Right Superior Vena Cava or the Right Azygous Vein

The pulmonary veins from each lung join to form a confluence posterior to the LA. An anomalous vessel originating from the right side of this confluence ascends, passes anterior to the hilum of the right lung, and enters the posterior aspects of the right SVC (Fig. 35.16A). In a rare case, the right-sided ascending pulmonary venous vessel connects to the azygous vein.

Figure 35.16. Echocardiographic delineation of totally anomalous pulmonary venous connection. A: High left parasternal transverse view of TAPVC to the right superior vena cava (SVC). The right upper pulmonary vein (RUPV), right lower pulmonary vein (RLPV), left upper pulmonary vein (LUPV) and left lower pulmonary vein (LLPV) are seen joining a horizontal pulmonary venous confluence (PVC). The vertical vein (asterisk) ascends rightward and anteriorly to join the posterior aspect of the SVC. The pulmonary artery (PA) is dilated secondary to the volume load. Ao, aorta.

Figure 35.16. (Continued) **B:** Subcostal oblique view with color Doppler comparison of TAPVC to the coronary sinus (CS), which is markedly dilated. The image depicts the typical “whale’s tail” appearance of the pulmonary venous confluence (PVC) and connection of the vertical vein (VV) to the CS. Note the obligate right-to-left shunt across the patent foramen ovale (PFO, arrow) and the small left atrium. (RA, right atrium.) **C:** Subcostal short-axis view with color Doppler comparison of infradiaphragmatic TAPVC in a patient with congenital absence of the left lung. From this view, the descending VV flow is demonstrated (red), with obstruction (arrow) at the point of connection with the IVC.

Connection to the Left Cardinal System

CONNECTION TO THE LEFT INNOMINATE VEIN

In this, the most common site of TAPVC, the pulmonary veins from both lungs form a confluence immediately posterior to the LA (Fig. 35.15A). A venous channel originates from the left portion of the confluence, usually passes anterior to the left pulmonary artery and mainstem bronchus, ascends into the superior mediastinum, passes anterior to the aortic arch, and joins the LIV proximal to its origin from the left jugular and subclavian veins (Fig. 35.17). The LIV then joins the right SVC in normal fashion. Less commonly, the ascending vein passes between the left pulmonary artery and left main

stem bronchus; the latter structures produce an extrinsic obstruction to pulmonary venous flow. The venous channel connecting the pulmonary vein to the LIV is an anomalous vertical vein that represents an embryonic channel between the splanchnic and the cardinal venous systems. Therefore, the term persistent LSVC should not be used for this venous channel (a persistent LSVC connects with the CS or with the LA when the CS is unroofed).

CONNECTION TO THE CORONARY SINUS

The entire anomalous pathway is situated within the pericardium. The pulmonary veins join a common vessel that connects to the CS in the region of the AV groove (Figs. 35.15B

Figure 35.17. Posterior view of heart and lungs specimen showing supracardiac totally anomalous pulmonary venous connection. The individual pulmonary veins form a horizontal confluence (Horizontal PV) behind the left atrium (LA). The left vertical vein (LVV) connects to left innominate vein, which continues into the right superior vena cava (RSVC). The VV is “sandwiched” between the left main stem bronchus posteriorly and the left pulmonary artery anteriorly. Note the poststenotic dilatation of the LVV. LL, left lung; LV, left ventricle; RL, right lung.

and 35.16B). The CS then follows its normal course to the RA. The enlarged orifice of the CS is either normally placed between the orifices of the IVC and tricuspid valve or is displaced posterior to the orifice of the IVC. The cardiac veins drain normally into the CS, which shares a common wall with the LA throughout the greater portion of its length. Stenosis at the junction of the common pulmonary vein with the CS or within the CS is rare but can occur.

Connection to the Umbilicovitelline System

This distal site of connection is situated below the diaphragm. The pulmonary veins from both lungs join to form a confluence immediately behind the LA. A common vessel originates from this confluence, descends immediately anterior to the esophagus, and penetrates the diaphragm through the esophageal hiatus. Most commonly, the anomalous descending vessel then joins the portal vein at the confluence of the splenic and superior mesenteric veins (Figs. 35.15C and 35.18). Less often, the anomalous vessel connects to the ductus venosus, to one of the hepatic veins, or to the IVC. When the anomalous connection is to the umbilicovitelline system, pulmonary venous obstruction is usually present.

Anatomic Sites of Obstruction to Pulmonary Venous Drainage

The presence of an obstructive lesion in the anomalous pulmonary venous channel profoundly influences the hemodynamic state and clinical features in a case of TAPVC. Some of the anatomic causes of obstruction are listed in the following sections.

Obstruction at the Interatrial Septum

Burroughs and Edwards (40) clearly related longevity in TAPVC to the size of the ASD. Those patients with large defects survived longer than did patients with restricted interatrial openings.

Figure 35.18. Posterior view of heart and lung specimen showing totally anomalous pulmonary venous connection to the portal vein. The ductus venosus is atretic at two locations (Inset) between the vertical vein and the suprahepatic segment of the inferior vena cava (IVC), and between the vertical vein and the confluence of the left umbilical and left portal veins. (From Delisle G, Ando M, Calder AL, et al. Total anomalous pulmonary venous connection: Report of 93 autopsied cases with emphasis on diagnostic and surgical considerations. *Am Heart J* 1976;91:99–122, with permission from Elsevier).

Obstruction in the Anomalous Venous Channel

Obstruction in the anomalous venous channel may be caused by several factors. Intrinsic narrowing in the walls of the anomalous vessels frequently occurs. Extrinsic pressure also results in narrowing of the venous structure. For example, when the vertical vein in TAPVC to the innominate vein passes between the left main pulmonary artery and left mainstem bronchus, the latter structures may obstruct the former (Fig. 35.17). Similarly, the anomalous pulmonary vein in TAPVC to the SVC may be obstructed by the right pulmonary artery and trachea. The ductus venosus normally undergoes constriction, and therefore anomalous connection to this structure results in pulmonary venous obstruction. Finally, when the anomalous connection is to the portal vein or one of its tributaries, the hepatic sinusoids are interposed in the pulmonary venous channel and result in increased resistance to pulmonary venous return. Another factor that may contribute to impedance of pulmonary venous return is the length of the ascending or descending vertical venous pathway.

Associated Cardiac Anomalies

Frequently, TAPVD occurs as an isolated anomaly in patients with normal viscerotransposition. It has been reported, however, to be associated with transposition of the great arteries,

tetralogy of Fallot, single ventricle, truncus arteriosus, tricuspid atresia, hypoplastic left heart syndrome, pulmonary atresia, multiple VSDs, coarctation of the aorta, vascular sling, and other anomalies (42). In contrast, TAPVD to the RA occurs, as a rule, in patients with visceral heterotaxy and polysplenia. Rarely, it is found in patients with visceral heterotaxy and asplenia as well. Hence, TAPVD may be associated with the various defects characterizing the heterotaxic patients, such as common AV canal, conotruncal anomalies, septal defects, pulmonary stenosis or atresia, mitral atresia, systemic venous anomalies, and others.

Microscopic Anatomy

Anomalous Vessels

Sherman and Bauersfeld (43) examined the anomalous venous vessels in eight patients and reported each to be altered by scarring. Fibrosis was abundant in the adventitia, and in some cases, there were focal areas of severe medial fibrosis. An intimal fibrous layer was noted in one. Unobstructed veins often exhibited vein wall atrophy or hypertrophy of intima, media-adventitia, or both. Obstructed veins usually have media-adventitial thickening and often have intimal proliferation.

Left Atrium

Sherman and Bauersfeld (43) reported that the histologic picture of the LA in 13 patients was atrophy. Although the muscle fibers were narrow with scanty cytoplasm, they had abundant nuclei. These investigators found that the number of muscle fibers in the LA in TAPVC approximated controls.

Lungs

The microscopic findings in the lungs vary depending on whether pulmonary venous obstruction is present.

TAPVC without Obstruction

In the absence of pulmonary venous obstruction, the muscular arteries and arterioles generally have prominent medial hypertrophy. Intimal lesions in the arterioles are uncommon in the infant but usual in the older child and adult.

TAPVC with Obstruction

In TAPVC with obstruction, there is medial hypertrophy within the anomalous venous channels, the extrapulmonary veins, and the small veins of the lungs. Pulmonary edema and extravasation of red cells into the alveolar spaces are pronounced. Prominent dilation of the subpleural and interlobular lymphatics is present, and medial hypertrophy of the pulmonary arterioles and pulmonary arteries is pronounced. Intimal proliferation within the arterioles is common, and necrotizing arteritis rarely is seen.

Physiology

All venous blood returns to the RA. Some form of communication between the right and left sides of the heart is essential for survival in TAPVC. The physiologic features depend on the distribution of this mixed venous blood between the pulmonary and systemic circulations. The state of the interatrial septum is of primary importance in this distribution. During fetal life, PBF is small, and the combined systemic and pulmonary venous return to the RA is only minimally increased. Hence, the stimulus for the development of a large interatrial communication is minimal. Some degree of restriction to

flow across a patent foramen ovale (found in 70% to 80% of cases) is common. In patients with a restrictive interatrial communication, the amount of blood reaching the LA is limited and systemic output is reduced. As pulmonary vascular resistance gradually decreases after birth and as demands for SBF increase with the rapid growth of the infant, massive pulmonary overcirculation ensues. Pulmonary and systemic venous blood return is to the RA; therefore, increased right atrial pressure results in pressure elevation and congestion in both venous circuits.

On the other hand, the presence of a widely patent foramen ovale or ASD allows free communication between the two atria. In this circumstance, the distribution of mixed venous blood depends on the relative compliance of the atria and ventricles and the relative resistance imposed by the pulmonary and systemic arterial circuits. The major variable is the state of the pulmonary vascular bed, which initially depends on the presence or absence of pulmonary venous obstruction.

TAPVC without Pulmonary Venous Obstruction

At birth, the distribution of blood between the pulmonary and systemic circuits is approximately equal because the resistance in these two vascular beds is nearly equal. In the first few weeks of life, maturation of the pulmonary vascular bed produces a decrease in pulmonary vascular resistance, and a progressively larger proportion of the mixed venous blood traverses the pulmonary circuit. PBF is commonly three to five times SBF. SBF is usually normal. Because the mixed venous pool receives three to five parts of fully saturated blood for each part of desaturated systemic venous blood, oxygen saturation in the RA may be $\geq 90\%$. Adequate mixing in the RA is the rule. Thus, oxygen saturation in the right ventricle, pulmonary artery, LA, left ventricle, and aorta is expected to be equal to that in the RA. Oxygen saturation in the systemic arteries may vary considerably, depending on the type of TAPVC (i.e., supracardiac, to the CS, or infradiaphragmatic), presumably as a result of the streaming of the mixed venous blood. Progressive dilation and hypertrophy of the right ventricle and dilation of the pulmonary artery usually occur.

Pulmonary artery pressure in infants ranges from slightly elevated to systemic. The state of the interatrial communication in patients with TAPVC without pulmonary venous obstruction has a major impact on PBF, pressure, and resistance. In the few patients who survive to older childhood or early adulthood, the pulmonary artery pressure is only slightly elevated. As time goes on, medial hypertrophy and intimal proliferation occur in the pulmonary arterioles, resulting in more severe pulmonary hypertension in the third and fourth decades.

TAPVC with Pulmonary Venous Obstruction

Elevated pressure in the pulmonary venous channels is transmitted to the pulmonary capillary bed. Pulmonary edema results when the hydrostatic pressure in the capillaries exceeds the osmotic pressure of the blood. Mechanisms that tend to prevent pulmonary edema include increased pulmonary lymphatic flow, alternative pulmonary venous bypass channels, altered permeability of the pulmonary capillary wall, and reflex pulmonary arteriolar constriction. The last mechanism results in a decrease in pulmonary flow, pulmonary hypertension, right ventricular hypertension and hypertrophy, and, ultimately, right heart failure.

The right ventricular volume and pressure overload result in a leftward shift of the interventricular septum that, together with the decreased inflow from the LA, lead to a decrease in left ventricular volume. Systemic output usually is low because of the inadequate filling volume.

Clinical Manifestations

The signs and symptoms in TAPVC are variable, depending on the underlying hemodynamics. When the interatrial communication is inadequate, symptoms occur at birth or shortly thereafter. The hemodynamic consequences of inadequate interatrial communication include pulmonary venous obstruction. The presence of intrinsic or extrinsic narrowing in the connecting vein also produces pulmonary venous obstruction. Thus, the manifestations may be divided according to whether pulmonary venous obstruction is absent or present.

TAPVC without Pulmonary Venous Obstruction

CLINICAL FEATURES

Patients are usually asymptomatic at birth. Seventy-four patients with TAPVC without pulmonary venous obstruction are present in the files of the Northern Great Plains Registry of Congenital Heart Disease (44). Of these, 56% had symptoms in the first month of life and the remainder in the first year. Tachypnea and feeding difficulties were the initial symptoms, usually manifested by the first few weeks of life. From that point on, the infants did not thrive, were subject to repeated respiratory infections, and usually had cardiorespiratory failure by 6 months of age.

Cyanosis may be so mild as to be clinically inapparent, except in the presence of cardiac failure and in the patient who survives long enough to acquire secondary pulmonary vascular changes. Of these infants, 75% to 85% die by 1 year of age, most in the first 3 months of life (40). The infants are thin and irritable and may exhibit slight duskeness on crying and exertion. Dyspnea, tachypnea, tachycardia, and poor feeding are almost always present.

A prominent right ventricular heave is a typical finding. A characteristic feature is the presence of multiple cardiac sounds. The first sound is loud and distinct and often is followed by a systolic ejection click. The second sound is widely split and does not vary with respiration. The pulmonary component of the second sound is accentuated. A third heart sound, maximal at the apex almost always, is present. A fourth heart sound is frequently heard in older patients. A cardiac murmur is occasionally absent. Characteristically, a grade 2/6 soft, blowing, systolic ejection murmur is heard in the pulmonary area. This murmur often is heard well over the xiphoid and at the lower left sternal border; in this case, it is S1 coincident secondary to tricuspid regurgitation. Turbulence in the pulmonary outflow tract or tricuspid valve insufficiency, or both, account for the systolic murmurs. A diastolic tricuspid flow murmur at the lower left sternal border occurs frequently. When the anomalous connection is to the LIV, a venous hum at the left or right base may be heard. Unlike the “innocent” venous hum, this murmur is not louder during diastole and is not altered by change in position or pressure on the neck veins.

Cardiac failure occurs in most patients prior to 6 months of age. In cardiac failure, hepatomegaly is always present, and peripheral edema is present in about half of the cases. Clubbing occasionally is seen in the patient who survives infancy.

ELECTROCARDIOGRAPHIC FEATURES

A tall peaked P wave in lead II or the right precordial leads characteristic of right atrial enlargement is a constant finding. Right-axis deviation is usual. Right ventricular hypertrophy invariably is present, usually manifested by high voltage in the right precordial leads and occasionally as an incomplete right bundle branch block pattern.

RADIOLOGIC FEATURES

Certain features are common to all cases. The lung fields reflect increased PBF. The RA and right ventricle are enlarged, and the pulmonary artery segment is prominent. The left-sided chambers are not enlarged. In addition, the specific site of anomalous connection may result in characteristic signs. A figure-of-8 or “snowman” appearance of the cardiac shadow is seen in patients with TAPVC to the LIV (Fig. 35.11). The upper portion of the figure-of-8 is composed of the anomalous vertical vein on the left, the LIV superiorly, and the SVC on the right. This diagnostic sign usually is not present in the first few months of life but often is present in the older child and adult. When the anomalous connection is to the right SVC, dilation of this structure results in a prominence at the upper right cardiac border.

ECHOCARDIOGRAPHIC FEATURES

The goals of the echocardiographic examination in TAPVC are (a) to establish the diagnosis; (b) to image and determine the size of the individual pulmonary veins; (c) to ascertain that all four major pulmonary veins join the pulmonary venous confluence and that no additional pulmonary veins drain separately; (d) to image and determine the size of the pulmonary venous confluence and its relation to the LA; (e) to image the course of the pulmonary venous channel (usually the vertical vein), its connection with the systemic vein, and its relation to neighboring structures (i.e., pulmonary arteries and airways); (f) to determine whether there is obstruction to pulmonary venous flow and its mechanism; (g) to evaluate the interatrial communication for obstruction; and (h) to perform a complete anatomic and functional survey of all cardiovascular structures and to exclude additional structural cardiac anomalies. These goals are achieved by performing a complete step-by-step echocardiographic examination from multiple windows.

The features common to all forms of TAPVC are signs of right ventricular volume overload. The right-sided heart structures are dilated. The RA is enlarged, and the atrial septum bows toward the left. The right ventricle appears to compress the left ventricle, the interventricular septum deviates leftward, and left ventricular volume is decreased. The interventricular septum may move paradoxically. The pulmonary arteries are dilated.

Aside from the features of right ventricular volume overload, the first echocardiographic suspicion that supports the diagnosis of TAPVC is the inability to image the pulmonary veins entering the LA. The LA is small. The pulmonary venous confluence usually is easy to recognize as an echo-free space behind the LA. Next, the individual pulmonary veins are sought. Once identified, each individual pulmonary vein is imaged by 2-D and is interrogated by color Doppler flow mapping. The course and diameter of each vein then should be determined. Jenkins et al. (45) showed that the size of the individual pulmonary veins at the time of initial diagnosis is a strong, independent predictor of survival in TAPVC. Smaller pulmonary veins were associated with poorer prognosis. Based upon a recent multicenter study from Europe investigators similarly found hypoplastic/stenotic pulmonary veins to be an independent risk factor for death (46). The individual pulmonary veins should be imaged from multiple windows, but the parasternal, subclavicular, and suprasternal notch views mostly are used (Fig. 35.16).

The size and orientation (i.e., horizontal or vertical) of the pulmonary venous confluence and its relationship with the LA are important for surgical planning. When all pulmonary veins connect to a horizontal confluence at approximately the same level, anastomosis of this confluence to the back wall of the LA is relatively straightforward. In contrast, when the pulmonary veins connect to a vertical confluence at different levels,

the repair is more challenging. The subcostal, parasternal, and suprasternal notch windows are most useful. Once the pulmonary venous confluence is characterized, the venous channel that connects with the systemic vein is followed by 2-D imaging and color Doppler flow mapping. In general, the venous channel in supracardiac TAPVC is best imaged from the precordial windows (Fig. 35.16A), and the venous channel in infradiaphragmatic TAPVC is best evaluated from the subcostal view (Fig. 35.16C). In supracardiac TAPVC, the venous channel should be examined for its relation with the branch pulmonary arteries and the bronchi. Obstruction may be caused by external compression or by intrinsic stenosis. The site of connection with the systemic vein, most frequently the LIV, is a common site of narrowing. In infradiaphragmatic TAPVC, the most common site of obstruction is at its connection with the portal or the hepatic vein. Often the pulmonary venous channel dilates proximal to the site of stenosis, a finding that should prompt a careful search for obstruction. Luminal narrowing associated with flow acceleration and turbulence by color Doppler characterizes pulmonary venous obstruction, regardless of its mechanism. Spectral Doppler is most useful. Pulmonary venous flow in an unobstructed vessel is characterized by a low-velocity, phasic laminar flow pattern with brief flow reversal during atrial systole. An increased flow velocity disturbed (turbulent) flow pattern, and loss of the phasic variations characterize obstructed pulmonary venous flow.

When TAPVC connects to the CS, the sinus is dilated and can be imaged easily from the subcostal, parasternal long-axis, or apical four-chamber view (Fig. 35.16B). The dilated CS bulges anterosuperiorly into the LA. Dilation of the CS also occurs in other conditions (persistent left SVC draining to CS); hence, imaging of the pulmonary veins draining into the CS is key to the diagnosis.

Infradiaphragmatic TAPVC usually connects to the portal venous system but can connect to the hepatic veins or to the IVC. The pulmonary veins converge into a common channel, which is located inferior to the LA immediately above the diaphragm. The common pulmonary venous channel may appear as a distinct chamber. It is best imaged from the subcostal short- and long-axis windows, with scanning from left to right and superior to inferior to identify the abdominal connection of the anomalously connecting vein (Fig. 35.16C). In a transverse plane, the descending aorta lies to the left and posteriorly, the IVC to the right and anteriorly, and the anomalous pulmonary venous channel in an intermediate position. The descending anomalous vein may be missed if it is compressed by a congested liver. Doppler interrogation is used to differentiate flow characteristics among the various abdominal vessels. Flow in the descending aorta has a systolic laminar profile in a direction away from the heart. Flow in the IVC is nearly continuous, phasic, and toward the heart. Flow in the common pulmonary vein is characteristic of the venous flow pattern, except the direction is away from the heart toward the abdomen.

In mixed TAPVC, multiple windows must be used to image the connections of at least four individual pulmonary veins. Suprasternal, parasternal, and subcostal windows, as described previously, should be used. The most common type of mixed drainage is connection to both the CS and the LIV.

With each type of TAPVC, a thorough echocardiographic study is necessary to identify coexisting cardiac anomalies. Errors in the identification of TAPVC are more frequent when there are coexisting mixed connection of the pulmonary veins and associated cardiac lesions.

Transesophageal echocardiography provides an alternative approach in patients with poor transthoracic windows. The need for transesophageal imaging in the newborn and young infant, however, is minimal because the transthoracic windows

are usually adequate. Transesophageal echocardiography has a greater role in the evaluation of patients after TAPVC repair, especially in an acute-care circumstance. MRI provides superior diagnostic capabilities in the evaluation of pulmonary veins and should be considered in patients who can be safely imaged by this modality.

Prenatal diagnosis of TAPVC is important for counseling parents, determining prognosis, and planning delivery at a center with facilities and expertise in neonatal pediatric cardiac surgery. Identification of the pulmonary venous connections is one goal of a fetal echocardiographic examination. The normal connection of some of the pulmonary veins to the LA is apparent from the four-chamber view of the fetal heart as well as from short-axis views. Because fetal PBF is less *in utero* than postnatally, it can be difficult to identify anomalous pulmonary venous connections. If one sees right ventricular and pulmonary artery enlargement out of proportion to the left ventricular and aortic size *in utero*, one should consider the diagnosis of TAPVC, especially when other cardiac lesions that can produce the same picture have been excluded (i.e., coarctation, left-sided obstructive lesions, arteriovenous malformations). The prerequisite to the prenatal diagnosis of TAPVC is a high index of suspicion and good-quality imaging of the pulmonary veins; clues to the prenatal diagnosis in one study of 11 cases included visualization of a pulmonary venous confluence behind the LA and a vertical vein (47). Unambiguous identification of a normal connection of some of the pulmonary veins to the LA excludes the diagnosis. The diagnosis of heterotaxy syndrome should prompt a meticulous evaluation of the pulmonary veins.

MAGNETIC RESONANCE IMAGING

The advent of new MRI and MRA techniques in recent years brings this diagnostic modality to the forefront of imaging of pulmonary venous anomalies (24). MRI provides a wide-field imaging of the pulmonary veins and blood flow within them as well as adjacent cardiovascular structures. Noncardiac structures, such as airways, lungs, spine, and abdominal organs, are also seen. MRA provides a 3-D dataset that encompasses all cardiovascular and noncardiac structures (Fig. 35.19). Multilevel steady-state free precession cine MRI in axial, coronal, and oblique planes is performed across the chest and demonstrates the dynamic nature of blood flow, cardiac chambers, and AV and semilunar valves. Cine PC is used to determine flow direction and to quantify flow velocity and flow rate.

Usually, MRI is not necessary in the initial evaluation of newborns and in the infant with TAPVC because echocardiography is accurate, portable, and readily available. MRI is indicated in infants with TAPVC only when echocardiography is inconclusive. In older patients and elective circumstances, MRI provides a superior alternative to ultrasound.

CARDIAC CATHETERIZATION

The accuracy of 2-D and Doppler echocardiography in identifying the presence and type of TAPVC nearly has eliminated the need for diagnostic cardiac catheterization and angiography in the diagnosis of TAPVC. Ninety-seven percent sensitivity and 99% specificity have been reported in the echocardiographic diagnosis of TAPVC, even before color Doppler became available (48). Diagnostic cardiac catheterization now rarely is performed to clarify problems unresolved by 2-D and Doppler echocardiography. The advent of MRI in recent years may obviate the need for diagnostic catheterization even further.

The venous site of anomalous connection may be identified if highly saturated blood is obtained from the LIV, right SVC, or CS. In TAPVC, the oxygen saturation in the RA usually

Figure 35.19. Mixed-type totally anomalous pulmonary venous connection (TAPVC). Maximal-intensity projection image from a gadolinium-enhanced 3-D magnetic resonance angiogram viewed from posterior in a 1-day-old newborn with mixed-type TAPVC. The left lower (LLPV), right upper (RUPV), and right lower (RLPV) pulmonary veins drain into a large pulmonary venous confluence that drains via a large vertical vein (VV) below the diaphragm to join the portal vein into the inferior vena cava (IVC). The left upper pulmonary veins (LUPVs) join a separate VV that drains into the coronary sinus (CS). The MRI examination was requested as an alternative to cardiac catheterization and angiography because of the complexity of the pulmonary venous anatomy and acoustic shadowing from the right lung. The MRI examination delineated the anatomy of all pulmonary veins as well as the intra-cardiac and extracardiac anatomy, and these findings were subsequently confirmed at surgery.

ranges between 80% and 95%, and saturations in the RA, right ventricle, pulmonary artery, LA, left ventricle, and systemic arteries are nearly identical. When TAPVC is to the LIV or right SVC, SVC blood preferentially flows into the tricuspid orifice and IVC blood preferentially shunts into the LA, resulting in a pulmonary artery oxygen saturation that may be higher than that in the systemic artery.

Pressure in the right ventricle and pulmonary artery ranges from slightly elevated to equal or higher than systemic pressure. Interpretation of atrial pressures, particularly in an attempt to determine the adequacy of the interatrial communication, is difficult. The presence of equal pressures in the two atria is probably an unreliable sign of a nonobstructive intera-

Figure 35.20. Catheter angiography of totally anomalous pulmonary connection. Levophase of a right pulmonary artery angiogram showing supracardiac TAPVC to the left innominate vein. HPVC, horizontal pulmonary venous confluence; VV, vertical vein.

trial communication. This phenomenon is most likely attributable to the fact that the compliances of the two ventricles are usually comparable, and their filling pressures are thus equal even in the face of a restrictive interatrial communication. A right atrial pressure ≥ 2 mm Hg in excess of left atrial pressure is more reliable in predicting a restrictive interatrial communication, but too often it occurs in the face of free communication between the atria. The only reliable way to assess the size of the interatrial communication is to measure it with a balloon catheter.

Selective pulmonary arteriography usually is diagnostic. Following injection and passage of opaque dye through the pulmonary fields, the dye collects in the pulmonary venous channels and clearly outlines the anomalous connection (Fig. 35.20). In TAPVC to the LIV, the vertical vein can be seen to originate from the area of the common pulmonary vein and to ascend to join the LIV. The latter is outlined in its course to the SVC.

TAPVC with Pulmonary Venous Obstruction

CLINICAL FEATURES

Pulmonary venous obstruction is usual when the venous connection is to the umbilicovitelline venous system. Pulmonary venous obstruction is present in about 50% of cases when the connection is to supracardiac structures (49). Obstruction in the anomalous venous channel occurs but is less common in patients with anomalous connection to the CS. Regardless of the site of pulmonary venous obstruction, the clinical profile is the same.

There were 43 cases of TAPVC with obstruction in the files of the Northern Great Plains Registry of Congenital Heart Disease (44). Of these patients, 72% presented in the first month of life and the remainder presented early in the first year. Symptoms usually did not appear in the first 12 hours of life, a finding that helped differentiate these patients from patients with respiratory distress syndrome. Once symptoms began, there was rather rapid progression to dyspnea, feeding difficulties, and cardiorespiratory failure.

Age at death ranged from 2 days to 4.5 months (36). When the anomalous connection is below the diaphragm, cyanosis

and dyspnea may be accentuated by straining and swallowing as a consequence of interference of pulmonary venous outflow by increased intra-abdominal pressure or impingement of the esophagus on the common pulmonary vein as it exits through the esophageal hiatus. The clinical course in patients with severely obstructed infradiaphragmatic TAPVC might be stormy with rapid development of severe respiratory distress and acidosis in the first hours of life.

Despite the alarming symptoms, the cardiovascular findings may be minimal. The heart is not enlarged and has no significant right ventricular heave. The second sound usually is split, and the pulmonary component is accentuated. A cardiac murmur often is absent, but, when present, it is usually a soft, blowing, systolic ejection murmur in the pulmonary area. Moist rales are usual at the lung bases. Hepatomegaly is almost always present, and peripheral edema often is associated.

ELECTROCARDIOGRAPHIC FEATURES

Right ventricular hypertrophy is invariably present. Unlike TAPVC without obstruction, however, right atrial enlargement is not a usual feature.

RADIOLOGIC FEATURES

The cardiac size is normal or nearly so. The lung fields have abnormal pulmonary vascular markings, characterized by diffuse, stippled densities that form a reticular pattern that fans out from the hilar regions. The cardiac borders often are obscured. Kerley B lines have been described, and prominence of the superior pulmonary veins is usual. The radiographic appearance is not diagnostic of TAPVC with obstruction because it also is associated with other causes of pulmonary venous obstruction.

ECHOCARDIOGRAPHIC FEATURES

The 2-D and Doppler findings are as described in the previous section on TAPVC without obstruction. It is important to perform a thorough Doppler interrogation of the individual pulmonary veins, the pulmonary venous confluence, and its insertion into the right-sided cardiac structure to look for the presence of obstruction. This is characterized by a high-velocity, continuous, and nonphasic venous flow profile.

MAGNETIC RESONANCE IMAGING

In the uncommon circumstance when echocardiography cannot provide all diagnostic information required for surgical planning, MRI provides an excellent complementary option. Given that infants with obstructed TAPVC are often in cardiorespiratory distress, the MRI examination should be streamlined to quickly provide the essential diagnostic information. The fastest approach is to obtain only a contrast-enhanced 3-D MRA, a procedure that requires only several minutes of scan time and can be accomplished in < 15 minutes “door-to-door” time. In stable patients, a more comprehensive examination is performed as described in the previous section on TAPVC without obstruction.

CARDIAC CATHETERIZATION

Diagnostic cardiac catheterization in patients with obstructed TAPVC rarely is indicated because of the accuracy of echocardiography. The procedure should be avoided as much as possible because it may aggravate the already compromised clinical condition of these patients and delay operation.

Oximetry may be helpful if fully saturated blood is obtained from the IVC or the SVC. Interpretation of oximetry must be cautious, however. On the one hand, PBF is decreased and its volume may not be sufficient to allow a high oxygen saturation when mixed with systemic venous blood. On the other hand, streaming of renal venous blood may result

in the appearance of highly oxygenated blood in the IVC. In a newborn with TAPVC to the portal venous system, blood obtained from the umbilical vein is fully saturated, confirming the diagnosis.

Right ventricular pressures usually are systemic or higher. Pressures in the RA usually are normal. Left atrial pressure also is normal but contrasts strikingly with the elevated pulmonary artery wedge pressure.

When the pulmonary arteriogram demonstrates TAPVC to the portal venous system, pulmonary venous obstruction may be assumed. Sites of obstruction also may be outlined when the anomalous connection is to other venous channels. If the cardiac catheter enters the anomalous venous channel, it may traverse the area of obstruction, thereby creating high-grade or complete obstruction to venous return. If selective injection of contrast material into the anomalous venous channel is contemplated in the patient with TAPVC with obstruction, the injection should be done by hand.

Differential Diagnosis

TAPVC without Pulmonary Venous Obstruction

In the infant with this condition, the differential diagnosis must include large VSD, PDA, truncus arteriosus, common atrioventricular (canal) septal defect (AVSD), and functional single ventricle without pulmonary stenosis. Unlike TAPVC, all these anomalies have radiographic and ECG evidence of left atrial and left ventricular hypertrophy. Multiple heart sounds are not usual, and the cardiac murmur is harsher and may be associated with a thrill. The counterclockwise frontal vector loop identifies common AVSD, as does the murmur of mitral regurgitation. The severity of the illness in the infant with suspected TAPVC warrants prompt echocardiographic examination, which will provide a definite diagnosis.

In the older child or adult with TAPVC, the differential diagnosis must include ASD, common atrium, and PAPVC. Common atrium and ostium primum ASD may be differentiated on the basis of a counterclockwise frontal vector loop. In the older patient, at least mild cyanosis is usually present in TAPVC, and this feature is absent in the usual case of secundum ASD or PAPVC unless pulmonary hypertension coexists. Nonetheless, a clinical distinction may be difficult in the older patient and will require special studies.

TAPVC with Pulmonary Venous Obstruction

Differential diagnosis in these infants includes the other causes of pulmonary venous obstruction as well as persistence of the fetal circulation. An accurate diagnosis should be achieved with a timely echocardiogram.

Treatment

Corrective surgery for the infant or child with TAPVC should be performed as soon as possible. In the sickest infants, the patient's clinical condition should be optimized, including the cardiorespiratory and metabolic states. Measures may include mechanical ventilation, inotropic support, diuresis, and correction of acidosis and other metabolic problems. When possible, surgery should be done on the basis of echocardiography because omitting cardiac catheterization speeds the time to operation, spares the infant the stress of this invasive procedure, and may reduce mortality.

Balloon atrial septostomy and blade atrial septostomy have been used as palliative procedures. Septostomy no longer seems appropriate because it delays the definitive procedure and is of little value when an anomalous venous channel

also is obstructed. Balloon dilation of obstructed anomalous venous channels was unsuccessful in the patients described by Lock et al. (50).

Operation for correction of TAPVC in infants < 1 year of age was associated with a mortality of about 50% through the early 1970s (49) and fell to 30% in the late 1970s (51). Bando et al. (52) reported the results of surgical repair of TAPVC in 105 infants from 1966 through 1995. Over time, the age at surgical repair has gradually decreased, as did operative mortality. From 1991 through 1995, none of the 31 operated infants died. Multivariate analysis showed that the only independent risk factor for death was a small pulmonary venous confluence. A more recent, larger multicenter cohort of 422 cases from European centers found the 3-year survival for those operated between 1998 and 2004 to be 85%, with independent risk factors for death in multivariate analysis comprised of earlier age at surgery, hypoplastic/stenotic pulmonary veins, associated complex cardiac lesions, postoperative pulmonary hypertension, and postoperative pulmonary venous obstruction (46). The surgical techniques for the specific anomalies are indicated in the following sections.

TAPVC to Coronary Sinus

The surgical technique for correction of TAPVC to the CS was described by Van Praagh et al. (27) in 1972. The common wall of the CS and LA is excised through a right atriotomy approach. This allows drainage of the pulmonary venous flow into the LA. The orifice of the CS is then closed either by direct suture or with the use of a patch. If present, an ASD should be closed as well. Rarely, the junction between the pulmonary veins and the CS can be stenotic. In such a case, the pulmonary venous obstruction must be addressed.

TAPVC to Left Innominate Vein

The basis of this correction is the creation of a large side-to-side anastomosis between the LA and the pulmonary venous confluence. Subsequent to the creation of the anastomosis, the ASD is closed, and the site of anomalous connection is ligated. Usually, a patch is used for ASD closure to ensure that the postoperative left atrial volume is normal. With minor modifications, this technique is used in correcting the TAPVC to the right SVC and TAPVC to the umbilicovitelline system.

An end-to-side anastomosis of the pulmonary venous confluence to LA often kinks. Use of the stump of the amputated left atrial appendage as a site for anastomosis often results in an inadequate opening because the diameter of the waist of the left atrial appendage is smaller than the diameter of the common pulmonary venous confluence (49).

Prognosis

Untreated

The prognosis in TAPVC is influenced by the size of the interatrial communication and by the presence of obstructing lesions in the anomalous venous pathways. The state of the pulmonary vascular bed, by determining the magnitude of the PBF, also plays a significant role in the prognosis.

In the survey by Keith et al. (53) involving TAPVC of all types, 50% were dead at age 3 months and 80% had died by 1 year of age. The figures reported by Burroughs and Edwards (40) are comparable. Patients with inadequate interatrial communication had an even poorer prognosis (40,52). When obstruction exists in the anomalous venous channel, the prognosis is grim. Death usually occurs within the first few weeks of life. In a series of patients with TAPVC with obstruction, the oldest survivor was 4.5 months old (36). The patients who

survive infancy often do so as a consequence of the protection provided by increased pulmonary vascular resistance, which is a mixed blessing and may jeopardize subsequent attempts at surgical repair. Far advanced intimal lesions in the pulmonary arterioles have been described as early as 8 months of age.

Postoperative Course

The long-term prognosis appears to depend mainly on the state of the pulmonary vascular bed at the time of operation and the adequacy of the pulmonary venous–left atrial anastomosis. In a series of 30 infants with TAPVC operated on between 1981 and 1991 (54) with a mean follow-up of 47 months, two late deaths and two reoperations occurred for pulmonary venous obstruction proximal to the anastomosis. The late deaths were due to persistent pulmonary hypertension in one and recurrent pulmonary venous obstruction in the other.

A similar hospital mortality rate of 13% was reported by Serraf et al. (55) in 30 infants with TAPVC operated on between 1985 and 1988. The cause of death was pulmonary hypertension in all four patients who died. The type of TAPVC, patient's age or weight, duration of cardiopulmonary bypass time, aortic cross-clamp time, or use of circulatory arrest did not affect the operative mortality. The mortality rate was affected by the preoperative status of the infant and the postoperative pulmonary artery pressure. Late pulmonary venous obstruction occurred in four patients for whom further therapy was advised. Reoperation was performed in two patients with one death, balloon dilation was successful in one patient, and the fourth patient died before reoperation. Residual stenosis at the left atrial–pulmonary venous anastomosis created at surgery was present in 8 of 68 patients (12%) reported by Yee et al. (56). These obstructions were relieved by patch plasty 1 to 24 months following the initial operation.

Sano et al. (57) operated on 44 infants with TAPVC. One operative death occurred secondary to postoperative suprasystemic pulmonary artery pressures. Of the remaining 43 patients, three developed recurrent pulmonary venous obstruction, and one developed SVC obstruction requiring reoperation within 2 months of the initial operation. Two of the three patients with recurrent pulmonary venous obstruction were found to have diffuse fibrosis of all lobar pulmonary veins as the cause rather than obstruction at the left atrial–pulmonary venous anastomosis. The patient with SVC obstruction had surgery and postoperatively developed bradycardia and sick sinus syndrome necessitating placement of a pacemaker. Lamb et al. (58) reported a series of 80 patients with TAPVC undergoing surgery. They noted the development of postoperative pulmonary venous obstruction in five patients (6%) 1.5 to 3 months after the initial operation. Five other children (6%) had reoperations, for residual shunts in four and for SVC obstruction in one.

Seale et al. (46) recently reported the results of an international, multicenter study of 422 patients with TAPVC, with an overall 3-year mortality of 15%; independent risk factors for death in multivariable analysis included earlier age at surgery, hypoplastic/stenotic pulmonary veins, associated complex cardiac lesions, postoperative pulmonary hypertension, and postoperative pulmonary venous obstruction. Sixty (15%) of these infants developed postoperative pulmonary venous obstruction, with 3-year mortality of 41% in this subgroup; risk factors for the development of postoperative pulmonary venous obstruction included hypoplastic/stenotic pulmonary veins at presentation and the absence of a common pulmonary venous confluence.

The postoperative development of pulmonary venous obstruction can be delineated with 2-D echocardiography combined with the use of spectral and color flow Doppler to identify and localize the area of obstruction. MRI and CT may

be particularly useful in the evaluation of pulmonary venous obstruction after TAPVC repair.

Late arrhythmias may develop in a small number of these patients. Atrial arrhythmias are most common and include sinus bradycardia, atrial flutter, and supraventricular tachycardia. Ventricular rhythm problems are unusual.

ATRESIA OF THE COMMON PULMONARY VEIN AFTER THE PULMONARY SYSTEMIC CONNECTIONS ARE OBLITERATED

Atresia of the Common Pulmonary Vein

In this anomaly, no communication exists between the normally formed pulmonary veins and the LA. In addition, there is no anomalous connection between the confluence of the pulmonary veins, on the one hand, and the heart or any systemic vein on the other hand. The physiologic consequence is severe obstruction to PBF. The condition appears to be rare. A pathologic review by Deshpande and Kinare (59) revealed three cases of atresia of the common pulmonary vein in a study of 1,326 autopsied hearts with congenital heart disease. Dudell et al. (60) diagnosed five cases in a 5-year period and documented 26 cases in the literature. Seale et al. (46) noted two cases of common pulmonary vein atresia in a study of 422 live-born infants with TAPVC.

Anatomy

The characteristic anatomic feature is the absence of a functional connection between the pulmonary veins and the LA or any other cardiac chamber or systemic vein. The normally formed pulmonary veins converge immediately behind the LA to form a blind cul-de-sac that has no outlet for pulmonary venous blood. Minor anatomic variations in the pulmonary venous system exist in some cases, including an atretic strand of tissue that may extend from one of the pulmonary veins to the RA or LA or an atretic fibrous strand that may connect the pulmonary venous confluence to a systemic vein. The lungs are firm and congested, and their pleural surfaces are remarkable in that the lobules are prominently outlined by edematous interlobular tissue and dilated lymphatic channels.

On microscopic examination, the pulmonary veins are thick-walled as a result of medial hypertrophy. The pulmonary arteries also reflect medial hypertrophy. The subpleural and interlobular lymphatics are markedly dilated, and the interlobular connective tissue is edematous. Large, dilated, irregular venous channels are also present in the parenchyma and interlobular areas. The alveoli contain many erythrocytes and iron-containing macrophages. Among the three cases reported by Deshpande and Kinare (59), there were two cases of atresia of the common pulmonary vein seen in association with asplenia syndrome, and one case had truncus arteriosus.

Physiology

Severe obstruction to pulmonary venous flow is present in this anomaly. PBF is markedly decreased and is even diverted away from the lungs by the right-to-left shunting at the atrial and the ductus arteriosus levels. Because these patients can live a few days to a few weeks, some means of blood flow from the lungs must exist. One must assume that an exit, however restricted, is provided by the bronchopulmonary veins carrying blood from the lungs to the systemic venous system. The features of severe pulmonary venous obstruction are comparable to those in TAPVC with venous obstruction.

Manifestations

Dyspnea and cyanosis appear shortly after birth. Death occurs in the first month. A thrill is not present. A grade 1 to 2 soft systolic ejection murmur along the left sternal border is usual, although a murmur may be absent. The ECG may be normal or show evidence of right ventricular hypertrophy. The usual chest radiographic picture of severe pulmonary venous obstruction is present. The pulmonary vascular markings have a diffuse reticular character. Cardiomegaly is minimal or absent.

Echocardiography

Echocardiographic demonstration of atresia of the common pulmonary vein was reported in three of five infants with this anomaly. We would anticipate that the echocardiographic findings would include right atrial, right ventricular, and pulmonary artery dilation and a small LA. Individual pulmonary veins would not return to the LA, and the common pulmonary venous confluence may be imaged behind the LA. The confluence would not connect to a right-sided cardiac structure. If PBF is limited, the ability to detect pulmonary venous flow by Doppler will be hampered. If the cardiac output is diminished, the Doppler flow in the aortic arch may be retrograde in systole. As a result of the pulmonary hypertension, a right-to-left shunt would be detected through the foramen ovale and ductus arteriosus by Doppler.

Cardiac Catheterization

Cardiac catheterization demonstrates severe pulmonary hypertension and marked systemic desaturation. Selective injection of contrast material into the right ventricle results in persistence of the contrast material in the pulmonary vascular bed and failure of opacification of the LA. Only rarely does contrast opacify the pulmonary venous confluence. If pulmonary arteriography is performed, the dye is shunted through the PDA into the thoracic aorta and usually does not opacify the pulmonary veins and the confluence.

Treatment

Some factors seem to favor successful surgical intervention. The anatomic problems are similar to those in cases of TAPVC, and anastomosis of the confluence of the pulmonary veins and the LA would afford a direct route for pulmonary venous drainage. The confluence of pulmonary veins is ample in size and is located directly behind the LA. The LA and left ventricle seem to be of adequate size, and complex cardiac anomalies are not present. Five infants have had successful surgical anastomosis of the common pulmonary venous confluence to the LA (60–62). Extracorporeal membrane oxygenation was an essential postoperative supportive measure in two of these patients (60).

Prognosis

Symptoms occur on the first day of life, and these patients follow a progressive downhill course to death within the first month of life when there is no surgical intervention. In too few cases has surgery been performed, usually with no follow-up period, to know the long-term outcome.

STENOSIS OF THE COMMON PULMONARY VEIN

Cor Triatriatum

In cor triatriatum, the pulmonary veins enter a pulmonary venous chamber that joins the LA through a narrow opening.

Alternatively, the pulmonary venous chamber may communicate with the RA directly or indirectly by way of an anomalous channel. Cor triatriatum is an unusual congenital anomaly, but it is probably not as rare as some reports indicate. The variety of anatomic expressions of cor triatriatum defeats an attempt to define a unified embryogenesis for all of them. The theory that abnormal growth of the septum primum accounts for cor triatriatum is difficult to reconcile with the observations of most workers in this field. Failure of incorporation of the common pulmonary vein into the LA is the most widely accepted theory of the embryogenesis of cor triatriatum. Some variants of cor triatriatum did not appear to be consistent with this theory, however. Other reports highlighted the embryogenetic complexities of this group of cardiac defects (63).

So-called cor triatriatum dexter is usually a persistence of the right valve of the sinus venosus. This section deals only with what is sometimes called cor triatriatum sinister.

Anatomy

The number of variants of cor triatriatum demands an inclusive classification (Table 35.3, Fig. 35.21).

PULMONARY VENOUS CHAMBER RECEIVES ALL PULMONARY VEINS AND COMMUNICATES WITH LEFT ATRIUM WITH NO OTHER CONNECTIONS

In classic cor triatriatum (Figs. 35.21A and 35.4), a membranous partition that has the shape of a windsock separates the more proximal chamber, which receives the pulmonary veins, from the more distal LA, which communicates with the mitral valve. The windsock is directed toward the mitral valve. The diameter of the orifice ranges from <3 mm to about 1 cm. There may be several small defects in the obstructive membrane (64). Histologically, the anomalous membrane contains cardiac muscle fibers and is occasionally calcified.

The more distal, true LA communicates with the left atrial appendage and in almost all cases has the fossa ovale lying between it and the RA. In many patients, no communication exists between either of the left atrial chambers to the RA (64).

TABLE 35.3 Anatomic Classification of Cor Triatriatum	
I. Pulmonary venous chamber receives all pulmonary veins and communicates with LA	
A. No other connections: classic cor triatriatum	
B. Other anomalous connections:	
1. To RA directly	
2. With totally anomalous pulmonary venous connection	
II. Pulmonary venous chamber receives all pulmonary veins and does not communicate with LA	
A. Anomalous connection to RA directly	
B. With totally anomalous pulmonary venous connection	
III. Subtotal cor triatriatum	
A. Pulmonary venous chamber receives part of pulmonary veins and connects to LA	
1. Remaining pulmonary veins connect normally	
2. Remaining pulmonary veins connect anomalously	
B. Pulmonary venous chamber receives part of pulmonary veins and connects to RA	
1. Remaining pulmonary veins connect normally	

Occasionally, a patent foramen ovale or an ASD allows the lower left atrial chamber to communicate with the RA. Right ventricular hypertrophy and dilation are found almost invariably, and right atrial hypertrophy and dilation are present in about 25% of cases (64).

Other Anomalous Connections

In a few cases, the pulmonary venous chamber communicates with the more distal true LA via a stenotic opening in the interatrial membrane and, additionally, with the RA through a defect between the RA and the pulmonary venous chamber (Fig. 35.21B). The pulmonary venous chamber may communicate indirectly with the RA through anomalous venous connections (Fig. 35.21C). Marin-Garcia et al. (65) reported findings on 20 patients with complete cor triatriatum communicating with the LA. In 12 patients, a classic diaphragm divided the LA. In three patients, an extrinsic constriction separated the pulmonary venous chamber from the LA (hourglass type), and in three there was obstructive tubular narrowing of the channel connecting the common venous confluence with the LA (tubular type). The hourglass and tubular types were all associated with complex cardiac lesions.

PULMONARY VENOUS CHAMBER RECEIVES ALL PULMONARY VEINS AND DOES NOT COMMUNICATE WITH LEFT ATRIUM

In this anomaly, the tissue separating the pulmonary venous chamber from the LA is intact and prevents the direct flow of pulmonary venous blood to the LA. A defect exists between the pulmonary venous chamber and the RA, and a patent foramen ovale allows communication between the RA and the lower, true LA (Fig. 35.21D). Pulmonary venous blood thus enters the pulmonary venous chamber, crosses the defect into the RA, and then traverses the foramen ovale to reach the true LA. In three of the six cases reported by Lam et al. (66), the defect was successfully corrected by excising the anomalous left atrial membrane and closing the ASD.

When there is no direct communication between the pulmonary venous chamber and the true LA, one of the alternatives for egress of pulmonary venous blood flow is TAPVC (Fig. 35.21E). Pulmonary venous blood entering the pulmonary venous chamber reaches the RA through the anomalous connecting vein and then enters the LA through a patent foramen ovale or ASD.

Subtotal Cor Triatriatum

The pulmonary venous chamber receives part of the pulmonary veins and connects to the LA. In this anomaly, the veins from one lung empty into a small pulmonary venous chamber that communicates with the true LA through a stenotic opening. The remaining pulmonary veins may connect normally to the LA (Fig. 35.21F) or they may connect anomalously to a systemic vein (Fig. 35.21G). Distinction of this anomaly from stenosis of individual pulmonary vein(s) at the left atrial junction can be challenging.

In another variant, the pulmonary venous chamber receives part of the pulmonary veins and connects to the RA (Fig. 35.21H). In this circumstance, the pulmonary veins from one lung empty into a small pulmonary venous chamber that communicates via a stenotic opening with the RA. The remaining pulmonary veins connect normally to the LA.

Microscopic Anatomy

When cor triatriatum obstructs pulmonary venous flow, the lungs reflect varying degrees of pulmonary edema and intraalveolar hemorrhage. There is medial hypertrophy of the pulmonary veins, and lymphatic channels are dilated. Pulmonary arterial lesions range from medial hypertrophy alone, to

Figure 35.21. Cor triatriatum variants. **A:** Classic cor triatriatum. Right and left pulmonary veins (RPVs and LPVs) drain to the pulmonary venous confluence (PVC), with discrete membrane between the PVC and true left atrium (LA); the only egress for blood is through the opening in the membrane. **B:** Cor triatriatum with defect between the PVC and the right atrium (RA), which allows for decompression of pulmonary venous blood. **C:** Cor triatriatum with decompressing vertical vein (VV) to the left innominate vein (LIV), which allows for decompression of the PVC. **D:** Pulmonary venous return decompresses via a communication between the PVC and right atrium, and then crosses to the true left atrium via a patent foramen ovale. **E:** Decompressing vertical vein that descends below the diaphragm to connect to the systemic venous circulation via the hepatic or portal veins. **F:** "Partial" or subtotal cor triatriatum with normally draining left pulmonary veins; the right pulmonary veins communicate with the true left atrium via a stenotic orifice. **G:** Subtotal cor triatriatum of the right pulmonary veins along with partially anomalous venous return of the left pulmonary veins via the left innominate vein. **H:** Subtotal cor triatriatum of the right pulmonary veins to the right atrium (RA) with normal drainage of the left pulmonary veins to the left atrium. (From Brown DW. Pulmonary Venous Anomalies. In: Lai, WW, Mertens LL, Cohen MS, Geva T, et al., eds. *Echocardiography in Pediatric and Congenital Heart Disease: From Fetus to Adult*. United Kingdom: Wiley-Blackwell, 2009:119–142, with permission).

medial hypertrophy with intimal proliferation, to necrotizing arteriolitis.

Physiology

In defects where the blood from the pulmonary venous chamber drains either directly or indirectly to the RA, the hemodynamic features are comparable to those seen in TAPVC and will not be considered further here. On the other hand, when there is no alternative pathway for pulmonary venous blood, the stenotic opening in the intra-atrial membrane dividing the pulmonary venous chamber from the LA results in elevated pressure in the former, which is transmitted to the pulmonary veins. The features of pulmonary venous obstruction pertain.

In the patient with subtotal cor triatriatum, the obstructive phenomenon affects only one lung. Reflex pulmonary arterial constriction in the affected lung will result in diminished flow through that lung; however, the remaining unobstructed lung

is usually capable of accepting increased blood flow, and thus pulmonary arterial pressure is not elevated.

Manifestations

The following sections consider the features of only classic cor triatriatum.

CLINICAL FEATURES

Most patients with classic cor triatriatum have onset of symptoms within the first few years of life. Nonetheless, some patients are asymptomatic until the second or third decade of life. Usually, the patients present with a history of breathlessness, frequent respiratory infections, and pneumonia.

The signs of pulmonary hypertension, including loud pulmonary component of the second heart sound, right ventricular heave, and pulmonary systolic ejection click, are most characteristic. The usual cardiac murmur is a soft, blowing, systolic

murmur along the left sternal border. Less often, a diastolic murmur is detected at the mitral area, or a continuous murmur is heard. Pulmonary rales are frequent. Right-sided heart failure is common in severe, untreated cor triatriatum.

ECCHOCARDIOGRAPHIC FEATURES

The advances in 2-D and Doppler echocardiography have simplified the noninvasive diagnosis of causes of pulmonary venous obstruction and increased its accuracy (Fig. 35.4). Cor triatriatum, by producing venous obstruction, results in dilation of the RA, right ventricle, and pulmonary artery. Imaging from the parasternal, apical, and subcostal windows allows assessment of the size of these cardiac chambers. These are nonspecific findings, also associated with TAPVC, coarctation, hypoplastic left heart syndrome, and critical aortic stenosis.

Two anomalies, cor triatriatum and supraventricular stenosing ring of the LA, create pulmonary venous obstruction by the presence of a membrane within the left atrial cavity. In both conditions, the membrane can be imaged as a linear echo-bright structure above the mitral valve in the LA. The membrane in cor triatriatum usually is curvilinear and may have the appearance of a windsock. A supramitral stenosing ring is located on the atrial surface of the base of the mitral valve leaflets and is relatively immobile. During diastole, the cor triatriatum membrane moves toward the mitral valve. The motion and appearance of the mitral valve are usually normal. The left atrial appendage and foramen ovale are located distal to the membrane of cor triatriatum, and the pulmonary veins insert into the proximal chamber. In contrast, the membrane in supraventricular stenosing ring of the LA is usually adherent to the mitral valve, moves away from the valve in diastole, and has the left atrial appendage and foramen ovale located proximal to the membrane. The mitral valve domes during diastole and has decreased excursion of the posteromedial leaflet.

Doppler interrogation of left atrial membranes may reveal disturbed diastolic flow profiles that may be best appreciated by color flow Doppler mapping. The flow profiles may mimic mitral stenosis.

ELECTROCARDIOGRAPHIC FEATURES

The typical finding is right ventricular hypertrophy. Right atrial hypertrophy results in tall, peaked P waves in some of the cases. Broad, notched P waves are present in some cases, presumably as a consequence of the dilated pulmonary venous chamber, but are absent in others.

RADIOLOGIC FEATURES

The routine chest radiogram reflects pulmonary venous obstruction. Fine, diffuse, reticular pulmonary markings fan out from the pulmonary hilum to involve the lower lung fields. Kerley B lines may be present. Prominent venous engorgement of the upper pulmonary veins results in the staghorn sign. The chest radiogram also reveals enlargement of the main pulmonary artery, right ventricular hypertrophy, and signs of "left atrial" enlargement, including posterior deviation of the barium-filled esophagus and a double density at the right cardiac border. These latter features are due to the dilated pulmonary venous chamber.

MAGNETIC RESONANCE IMAGING

This is another noninvasive imaging modality that can delineate the left atrial membrane of cor triatriatum. MRI may be helpful in defining the cause of pulmonary hypertension when echocardiography is not diagnostic.

CARDIAC CATHETERIZATION

Pulmonary hypertension routinely is found. Using oximetry one can exclude a left-to-right shunt. Thus, pulmonary hypertension is either caused by primary pulmonary vascular

disease or secondary to pulmonary venous obstruction. The pulmonary arterial wedge pressure is elevated, and left atrial pressure is normal.

Selective pulmonary arteriography usually demonstrates cor triatriatum. Pulmonary transit time is prolonged. As the pulmonary veins opacify, they drain into an accessory left atrial chamber. There is usually a delay between the opacification of this chamber and the opacification of the true LA and left ventricle. Moreover, in some cases, the intra-atrial membrane can be identified as a linear or cone-shaped filling defect between the pulmonary venous chamber and the true LA. The pulmonary venous chamber remains opacified for some time and does not change size or contour with cardiac contractions as does a normal LA (67).

Differential Diagnosis

The differential diagnosis differs depending upon the age of the patient. In the infant or young child, the differential diagnosis lies within the group of cardiac anomalies that produce pulmonary venous obstruction.

In the adult, cor triatriatum should be distinguished from primary pulmonary hypertension. In addition, the differential diagnosis includes congenital and acquired mitral stenosis, supramitral stenosing ring, left atrial tumor, and left atrial thrombus. In the adults with cor triatriatum reviewed by McGuire et al. (68), four of eight had a mitral diastolic murmur, but none had the typical presystolic crescendo rumble of mitral stenosis. Likewise, no case had an opening snap. The absence of broad and notched P waves was another feature distinguishing cor triatriatum from mitral stenosis. Atrial fibrillation, commonly seen in mitral stenosis of comparable severity, was observed in only one of eight patients with cor triatriatum.

Treatment

Surgical resection of the obstructive membrane is indicated in patients with cor triatriatum and elevated pulmonary artery pressure.

Prognosis

The prognosis of cor triatriatum is related to the size of the orifice in the obstructing membrane. In Niwayama's survey (64), average survival was 3 1/3 months when the opening was <3 mm, and 16 years when the opening was >3 mm. When pulmonary edema and right heart failure occur, survival is usually only a matter of months.

In patients who survive operative correction, the prognosis seems excellent. The severe pulmonary arterial changes that result in pulmonary hypertension have been reversible in the patients studied postoperatively (26,27).

ABNORMAL ABSORPTION OF THE COMMON PULMONARY VEIN INTO LEFT ATRIUM

Stenosis of the Individual Pulmonary Veins

Two varieties of this unusual cardiac anomaly are recognized. In localized stenosis of the pulmonary veins, one or more of the pulmonary veins has a localized stenosis at its junction with the LA. The other variety is characterized by narrowing of the lumen of the pulmonary veins for a considerable distance in their intrapulmonary and extrapulmonary portions; this condition may be termed diffuse pulmonary veins stenosis or hypoplasia.

Localized stenosis of the individual pulmonary veins may be an isolated phenomenon, or it may be associated with a

minor or major cardiac anomaly. Reye (69) first described this anomaly in 1951. Shone et al. (70) have defined a characteristic angiographic feature that should allow a premortem diagnosis of this condition.

Diffuse stenosis or hypoplasia of the individual pulmonary veins is occasionally present in patients with pulmonary artery atresia or hypoplastic left heart syndrome. Seale et al (71) reported a series of 58 cases of pulmonary vein stenosis, with a history of prematurity found in 38%, and associated cardiac lesions in 79%. A significant extracardiac anomaly or syndrome was present in 28% of this cohort. The majority (62%) presented with unilateral pulmonary venous involvement, of which 86% was on the left.

The factors that favor a congenital cause were summarized by Shone et al. (70). The embryologic basis for stenosis of the individual pulmonary veins appears to be abnormal incorporation of the common pulmonary vein into the LA.

Anatomy

Krabbil and Lucas (72) studied examples of stenosis, hypoplasia, or atresia of individual pulmonary veins found in the Jesse Edwards Registry of Cardiovascular Pathology. After excluding complex left-sided obstructive lesions, mitral valve abnormalities, and cor triatriatum, eight examples remained. All pulmonary veins entered the LA in each case. Two cases had an associated common AVSD, one had Ebstein anomaly of the tricuspid valve, and the five remaining cases had no associated congenital cardiac anomalies. All pulmonary veins were obstructed in two cases, three of four pulmonary veins were obstructed in three specimens, and the veins of only one lung were obstructed in three specimens. Obstruction was produced by three different mechanisms. In four cases, the obstruction was due to a discrete area of medial hypertrophy or intimal proliferation of the affected pulmonary vein at its left atrial junction. Atresia of the pulmonary vein at its junction with the LA occurred in two cases. Hypoplasia of the pulmonary vein, which extended from the hilum of the lung to the LA, was present in two cases.

In addition to the extraparenchymal pulmonary vein obstruction, seven of eight cases had intimal proliferation involving the intraparenchymal pulmonary veins. In two of these, small veins in the unobstructed lung, as well as the veins in the obstructed lung, were stenotic. Others have noted the association of intimal proliferation in the small intraparenchymal pulmonary veins in both obstructed and unobstructed lobes. Sadr et al. (73) found abnormal intimal spindle-shaped cellular proliferation in all tissue specimens from 10 patients with pulmonary veins stenosis. In three of the four patients in whom immunohistochemical staining was available, there was evidence that the proliferating cells were myofibroblasts. Subsequent work by Riedlinger et al. (74) with autoantibodies directed against multiple cellular proteins and signaling ligands in intimal cells from seven patients with pulmonary vein stenosis demonstrated strong diffuse immunoreactivity for smooth muscle markers, as well as expression of receptor tyrosine kinases and other ligands. This work suggests an autocrine or paracrine role of these proteins in the pathogenesis of this disease.

The frequent occurrence of small pulmonary vein obstructive lesions may be responsible in part for the poor operative results in patients with stenosis of the individual pulmonary veins. In most of the cases reported in the literature, medial hypertrophy of the pulmonary arterioles is present. These pulmonary arteriolar changes occur in both the obstructed and unobstructed lung.

Manifestations

Clinical Features

Patients present with history of persistent tachypnea and recurrent pneumonia, ultimately progressing to right-sided

heart failure. They frequently exhibit failure to thrive and have hemoptysis. Most are cyanotic. The physical examination is consistent with signs of pulmonary hypertension, including a right ventricular heave and accentuation of the pulmonary component of the second heart sound. A short systolic murmur is the usual finding, and in the case reported by Shone et al. (70), a pulmonary systolic click was heard.

Echocardiographic Features

The distal portions of the pulmonary veins and their insertion into the LA are best imaged from suprasternal, high parasternal, or subcostal windows. The reflective nature of the air in the lungs limits the ability of ultrasound to image more proximal portions of the pulmonary veins. Discrete areas of narrowing or areas of hypoplasia may be noted in the distal pulmonary vein and at the pulmonary vein-LA junction. When pulmonary venous obstruction or stenosis of individual pulmonary veins is in the differential diagnosis, identification of each pulmonary vein is necessary. Normally, pulmonary vein flow is nearly continuous and phasic, with a short period of flow reversal following atrial contraction. In contrast, stenotic pulmonary veins have a continuous, high-velocity turbulent flow pattern without phasic variation.

Electrocardiographic Features

Right ventricular hypertrophy is usual, and right atrial enlargement may be present.

Radiologic Features

The heart is not greatly enlarged but reflects right ventricular hypertrophy. The pulmonary artery segment is enlarged, and the characteristic reticular markings of pulmonary venous obstruction are usual (70). The heart shifts toward the side of major involvement with pulmonary venous stenosis. The pulmonary vascularity will be asymmetric, with increased vascularity seen in the unaffected lung segments. Technetium-99m lung perfusion scans will show absence or diminished perfusion of the lung segments with pulmonary vein stenosis.

Magnetic Resonance Imaging and Computed Tomography

Both MRI and CT are ideally suited to evaluating pulmonary veins stenosis (Fig. 35.22A). CT is particularly helpful in the evaluation of abnormalities of the lung parenchyma.

Cardiac Catheterization

Right-sided heart catheterization reflects pulmonary hypertension. If the pulmonary veins are obstructed from only one lung, there will be an elevation of the pulmonary capillary wedge on that side. Angiography demonstrates prolonged transit time of opaque dye through the lung. The angiogram in the case reported by Shone et al. (70) clearly demonstrated the constriction at the pulmonary vein-left atrial junction and delayed emptying of the pulmonary veins (Fig. 35.22B).

Treatment

Operative management of stenosis of the individual pulmonary veins is disappointing, which may be related to the coexistence or progression of obstruction into the intraparenchymal pulmonary vein (long-segment stenosis/hypoplasia). An occasional patient with stenosis of the individual pulmonary veins involving only one lung has had successful reanastomosis of the stenotic veins to the LA, and some have benefited from pneumonectomy. The poor results of operation in stenosis of the individual pulmonary veins led to attempts to improve obstruction with transcatheter approaches, from simple balloon angioplasty (75,76) to cutting balloon dilation (77,78), and stent placement (79), including drug eluting stents. Several series have demonstrated effective short-term relief of stenosis with transcatheter techniques, but nearly universal recurrence

Figure 35.22. Pulmonary vein stenosis. **A:** Maximal-intensity projection image from a gadolinium-enhanced 3-D magnetic resonance angiogram (MRA) in a 21-year-old man with severe bilateral pulmonary vein stenoses (arrow). The patient was referred for MRI examination to rule out constrictive pericardial process after an evaluation by echocardiography and cardiac catheterization at another institution did not find a cause for the patient's severe pulmonary hypertension. The MRI findings were subsequently confirmed at cardiac catheterization in which balloon dilations of the pulmonary veins stenoses were performed. **B:** Catheter angiogram in a 3-month-old infant with heterotaxy syndrome, dextrocardia, and supracardiac TAPVC that had been repaired with anastomosis of the pulmonary venous confluence to the posterior aspect of the common atrium. Angiogram with catheter in the left upper pulmonary vein (LUPV) demonstrates the severe, discrete narrowing of the LUPV at the junction with the pulmonary venous confluence (arrow), with narrowing to the diameter of the catheter (1.2 mm). Note the lack of involvement of the proximal LUPV in the obstruction.

of obstruction. Newer surgical techniques including “sutureless” procedures to unroof the pulmonary veins at the junction with the LA may be slightly more successful than previous techniques (80), but the long-term prognosis for patients with pulmonary vein stenosis remains poor. Lung transplantation has been reported as well and may be curative (81).

Tal Geva

The word *vein* stems from the Latin *vena* (from the Latin verb *venio*, “to come”). Hence, a vein is a passage, a conduit, a vessel that brings blood to the heart regardless of the consistency of the blood it carries. A single exception is the portal vein, which carries blood from the intestine to the liver before its return to the heart through the hepatic veins. The spectrum of systemic venous anomalies varies widely from minor asymptomatic anatomic variations to complex abnormalities that can lead to cyanosis or that might complicate surgical repair of congenital heart disease. Clinically significant abnormalities of the systemic veins are infrequent when viscerotransposition is lateralized (either situs solitus or situs inversus). In contrast, the incidence of systemic venous anomalies in patients with heterotaxy syndrome exceeds 90% (1,2). The advent of pediatric cardiac surgery and interventional cardiology heightened interest in these anomalies. Consequently, in-depth understanding and accurate diagnosis of abnormal systemic venous connections have become essential for successful management of many congenital cardiovascular anomalies.

As with all congenital heart disease, understanding the anatomy of the systemic veins and its variations is greatly facilitated by reviewing its embryology. In considering the wide range of abnormalities of the systemic veins, an anatomic classification based on developmental principles provides a solid framework. In this chapter, the embryology of the systemic veins is reviewed first to provide a background for further discussion of specific venous anomalies. These have been categorized into the following groups: anomalies of the superior vena cavae, anomalies of the coronary sinus, anomalies of the inferior vena cava (IVC), anomalies of the ductus venosus, and anomalies of the sinoatrial valves.

EMBRYOLOGY

There are three basic venous systems in the human embryo: (a) the cardinal veins and their tributaries, which form the superior and inferior caval systems; (b) the umbilical, vitelline, and omphalomesenteric veins, which carry the blood from the placenta, yolk sac, and intestine; and (c) the pulmonary veins, which return the blood from the lungs.

The age of human embryos cannot be estimated reliably on the basis of their length, which may vary greatly (3), or on the number of somites, which are visible for only a limited time. In 1942, therefore, Streeter (4) proposed classifying human embryos into 25 age groups, or horizons, each representing 2 days of embryonic life. He later omitted the last two stages because he thought that stage XXIII could be considered the last stage of embryonic development. This approach generally has been accepted.

This chapter is dedicated to the late Dr. Stella Van Praagh, my teacher, mentor, and friend, who coauthored this chapter in the sixth and seventh editions of this textbook.

Normal Development of the Cardinal and Umbilicovitelline Venous Systems

The sinus venosus, that is, the cavity into which all veins eventually drain, develops by enlargement of the confluence of the umbilical veins and joins the atrial segment of the heart through a slit-like opening, the sinoatrial foramen. It already is present in the 20 somite embryo (horizon XI) (Fig. 36.1). It is composed of a middle section, which has been called the transverse sinus, and right and left sections, which have been named the right and left horns of the sinus venosus. The three main paired venous systems of the embryo—the cardinal, the umbilical, and the vitelline veins—drain into the ipsilateral horns of the sinus venosus.

The right and left umbilical veins develop first. They can be recognized during the third week of gestation in embryos of 13 somites (Fig. 36.1). At the same time, the vitelline plexus of the liver is formed and soon becomes more prominent on the right side. It will connect with the sinus venosus through the right hepatocardiac channel, which drains into the right horn of the sinus venosus and with the yolk sac via the left omphalomesenteric vein (Fig. 36.1).

The anterior cardinal veins make their appearance shortly after the umbilical and the vitelline veins (horizon XI, 22 to 24 days of gestation) (Fig. 36.2A,B). They drain blood from the fused neural folds that form the central nervous system. Soon after, the posterior cardinal veins appear lateral to the spinal cord. They join the anterior cardinals to form the right and left common cardinals (ducts of Cuvier) and drain together with the umbilical and vitelline veins into the right and left horns of the sinus venosus. Each horn of the sinus venosus drains for a short time into its respective sides of the common atrium (Fig. 36.1, stage of 20 somites).

At the beginning of the fourth week of embryonic life, an invagination appears between the left horn of the sinus venosus and the left atrium (LA) and ultimately separates the left horn from the LA. A rightward shift of the transverse portion of the sinus venosus that follows the appearance of the aforementioned invagination will complete the anatomic isolation of the LA from the three pairs of veins that enter the sinus venosus (cardinals, umbilicals, and vitellines). These veins will now drain into the right atrium (RA) through the sinoatrial foramen (Fig. 36.1, stage of 28 somites).

Normal Development of the Right Superior Vena Cava and the Coronary Sinus

The right superior vena cava (RSVC) extends from the confluence of the right and left innominate veins (RIV, LIV) to the RA. It is composed of the most proximal part of the right anterior cardinal vein and the right common cardinal vein. The development of the LIV at the seventh week of gestation usually is followed by the involution of the left SVC (LSVC),

Figure 36.1. Drawings made from models of human embryos (horizons XI–XIII, 13–30 somites [S]) showing the venous end of the heart viewed from the front. The ventricular part of the heart is removed at the atrioventricular junction (A-V Jct.). It can be seen that the atria are new formations, superimposed on the vitelline plexus (Vit. Plexus). The sinus venosus retains more definitely its identity with the vitelline plexus, taking on the character of a reservoir into which all the veins of the embryo drain. The venous blood then flows into the right atrium through the sinoatrial foramen (Sino-Atr. Foramen). This foramen marks the boundary between veins and heart proper. L. Atr., left atrium; L.C.C., left common cardinal vein; L.O.-M.V., left omphalomesenteric vein; L.U.V., left umbilical vein; R. Atr., right atrium; R.C.C., right common cardinal vein; R.U.V., right umbilical vein. (Modified from Streeter GL. Developmental horizons in human embryos: description of age group XI, 13 to 20 somites, and age group XXII, 21 to 29 somites. *Carnegie Inst Contrib Embryol* 1942;30:211–245.)

which becomes the ligament of Marshall (5). As the transverse segment of the sinus venosus shifts rightward, it pulls the left horn of the sinus venosus along the posterior atrioventricular groove. The left horn of the sinus venosus and the adjacent part of the common cardinal vein receive the cardiac veins and form the coronary sinus. The mode of formation of the coronary sinus is responsible for the following anatomic observations, which are helpful in making a diagnosis of certain congenital heart defects:

1. The orifice of a normally formed coronary sinus is always in the anatomically right atrium.
2. A persistent LSVC always continues with the coronary sinus since the left common cardinal vein is part of the coronary sinus and of the LSVC.
3. Functional connection (i.e., drainage) of a persistent LSVC or any other vein with the anatomically LA can occur only if the coronary sinus is partly or completely unroofed.

Normal Development of the Inferior Vena Cava

The IVC, the largest vein of the human body, is formed by the contribution of five different venous systems. The following description is a simplified version of a rather complex process. The posterior cardinal veins appear first, shortly after the establishment of the anterior cardinal veins. They

develop as longitudinal vessels running in the dorsolateral portion of the urogenital fold and are associated primarily with the mesonephroi (wolffian bodies) (Figs. 36.2 and 36.3) (6). The subcardinal veins are a new venous plexus, which initiates the diversion of the venous drainage of the mesonephroi and the developing urogenital system of the embryo. They are established along the ventromedial borders of the mesonephroi medial and ventral to the posterior cardinals (Fig. 36.3) (6). They have many channels connecting them with the posterior cardinals. As the mesonephroi increase in size and bulge toward the midline, the subcardinals are brought closer together. In the midmesonephric region, they establish communications with each other by several small vessels, which become confluent to form intersubcardinal anastomoses and eventually a large medial venous space, the subcardinal sinus (Figs. 36.2C and 36.3). When the subcardinal sinus is established, the small vessels that connect the subcardinals with the posterior cardinals drain medially into the subcardinal sinus rather than laterally toward the posterior cardinals. This will result in the diminution and the later disappearance of the posterior cardinals at the level of the subcardinal sinus.

The blood from the posterior part of the body is still collected by the distal part of the postcardinals but returns to the heart by way of the subcardinal sinus (Figs. 36.2C and 36.3). As the embryo grows, the blood volume that enters the

Figure 36.3. Diagram showing the anterior and posterior cardinal veins (Post Cardinal V.), the subcardinal veins (Subcardin. V., shaded), and the position of the wolffian bodies (mesonephroi) in the fifth week of gestation (left panel). The right panel shows the anastomoses between the anterior cardinal (Ant. Cardin.) veins (left innominate vein [left Innom. V.]), the inferior end of the posterior cardinal veins (left common iliac vein), and the intersupracardinal anastomosis with the hepatic veins (caval anastomosis [Caval Anastom.]) in the seventh week of gestation. (From Keith A. *Human Embryology and Morphology*. Baltimore, MD: Williams & Wilkins, 1948;433.)

subcardinal sinus increases and stimulates development of a new unpaired venous channel. This large unpaired venous channel, called the hepatic segment of the IVC, lies in a notch along the dorsal aspect of the liver (Fig. 36.2C,D). It is formed by a confluence of the small vessels that appear in a fold of the dorsal body wall just to the right of the dorsal mesentery. This fold is known as the caval fold of the mesentery. Connections of these small vessels with the plexus of the liver cephalically and the mesonephroi via the subcardinal sinus caudally allows the blood to flow from the mesonephroi to the liver plexus, resulting in rapid enlargement of this channel (6). By the seventh week of gestation, this new unpaired venous channel connects the subcardinal sinus with the confluence of the hepatic veins and the ductus venosus. The resulting large vessel constitutes the suprahepatic segment of the IVC, which enters the RA (Fig. 36.4).

At this stage, the posterior cardinals have involuted to the level of the common cardinals proximally and the iliac veins distally. Dorsal to the subcardinal sinus, a new set of paired veins appear: the supracardinal veins (Fig. 36.2D). These veins connect the subcardinal sinus with the cephalic remnant of the posterior cardinals via the azygos and hemiazygos veins. They also connect the subcardinal sinus with the iliac veins via the caudal remnant of the posterior cardinal veins. Eventually, the infrarenal portion of the left supracardinal vein will involute, and the infrarenal portion of the right supracardinal vein will become the infrarenal portion of the IVC (Fig. 36.2E,F).

By the seventh week of gestation, venous channels have been established to connect the left side with the right side of the paired veins. Proceeding from cephalad to caudad, these channels are the LIV, the hemiazygos, the left renal vein, and the left common iliac (Fig. 36.2F). The development of the

connecting channels is followed by partial involution of the left side of the paired veins. All venous blood, with the exception of the pulmonary venous return, now enters the right-sided SVC and IVC, which bring it to the RA.

In summary, the five venous systems that contribute to the formation of the IVC, from distal to proximal, are the posterior cardinals, the right supracardinals, the subcardinals, the hepatic segment of the IVC, and the hepatic (former vitelline) veins. Four of these five venous systems begin as bilateral venous channels, a fact that makes possible the existence of partly bilateral IVCs above the liver or below the kidneys (Fig. 36.5).

Normal Development of the Ductus Venosus

The paired umbilical veins, when first established, connect the placenta with the right and left horns of the sinus venosus. As the liver grows, it fuses with the lateral body wall. At the site of this fusion, multiple vessels develop, connecting the umbilical veins with the liver plexus (6). The umbilical stream tends to pass by way of these vessels into the liver, and the early direct connections of the umbilical veins with the sinus venosus involute. Distal to their entrance into the body of the embryo, the umbilical veins fuse. Consequently, there is only one vein in the umbilical cord. Inside the embryo, the right umbilical vein involutes except for a small segment that drains the body wall (Fig. 36.4). As the embryo grows and the volume of the umbilical venous blood increases, a new large channel is created through the liver substance, the ductus venosus, which connects the left umbilical vein with the right hepatic veins (Fig. 36.4). By the seventh week of gestation, placental blood finds its way to the RA by way of the left umbilical vein, the ductus venosus, and the suprahepatic segment of the IVC (Fig. 36.4). As it passes through the liver, the ductus venosus receives blood flow from the right and left hepatic veins and delivers it into the RA. After birth, the ductus venosus becomes the ligamentum venosum and the left umbilical vein becomes the ligamentum teres (round ligament of liver).

Azygos and Hemiazygos Veins

The azygos (“unpaired,” Greek) vein connects the suprarenal segment of the IVC with the right SVC (RSVC). It is formed by the suprarenal segment of the right supracardinal vein and the cephalic remnant of the right posterior cardinal vein (Fig. 36.2D–F). In the older literature, it was referred to as the vena azygos major. It commences from the right lumbar or the right renal vein or the IVC and passes through the aortic opening of the diaphragm to enter the thorax. It runs up medial to the thoracic vertebrae, to the right of the aorta and the thoracic duct, and receives the lower ten right intercostal veins. At the level of the fourth thoracic vertebra, it arches anteriorly to connect with the posterior surface of the SVC (Fig. 36.6) (7).

The hemiazygos (“half azygos”) vein has two parts: The first is the left lower, or smaller, azygos vein (vena azygos minor), which starts at the lumbar region from one of the lumbar veins or from the left renal vein, passes through the left crus of the diaphragm, and ascends on the left side of the spine up to the level of the ninth thoracic vertebra (Fig. 36.6). It then turns to the right behind the aorta and the thoracic duct to terminate into the azygos vein. The left upper hemiazygos varies inversely with the size of the left superior intercostal vein. It receives the left intercostal veins that did not drain into the left superior intercostal vein and the lower hemiazygos and terminates in the right azygos or the lower hemiazygos. In some cases with bilateral SVCs, bilateral azygos veins

may be present. It is obvious that the term bilateral azygos (i.e., bilaterally unpaired veins) is literally incorrect. It is also incorrect to use the term hemiazygos (i.e., half azygos) for a vein that extends from the suprarenal segment of the IVC to the LSVC. In current literature, both terms are used according to individual preference. We prefer to use the term left azygos vein rather than hemiazygos to indicate the course and length of this vein.

Normal Development of the Portal Vein

Venous return of the primitive gut circulation is by way of the vitelline veins of the yolk sac that become confluent with the right and left omphalomesenteric veins, which enter the sinus venosus posteriorly (Fig. 36.4). As the omphalomesenteric veins approach the heart, they lie adjacent to the developing liver. The proximal portion of the omphalomesenteric veins breaks

up into a maze of small channels ramifying through the liver substance. The distal portion brings blood from the yolk sac and the intestine to the liver. When the yolk sac disappears and the intestine grows, the omphalic (yolk sac) portion of these veins also disappears. The mesenteric part persists and grows to match the length and complexity of the growing intestine (6). By the sixth week of gestation, the paired mesenteric veins have formed anastomoses with each other. A week later, the left mesenteric vein involutes cephalad to the anastomosis, while the right mesenteric vein involutes caudal to the anastomosis. This results in the unpaired hepatic portal vein that connects the veins of the intestine and the spleen with the circulation of the liver.

ANOMALIES OF THE SUPERIOR VENAE CAVAE

Bilateral Superior Venae Cavae with Normal Drainage to the Right Atrium

Persistence of the LSVC is thought to result from failure of the left anterior and left common cardinal veins to involute (5). Descriptions of persistent LSVC date back to 1787 (8). In 92% of cases, the LSVC drains into the RA through the coronary sinus (9). In the remainder, it drains into the LA by means of a partially or completely unroofed coronary sinus. The incidence of persistent LSVC in two large autopsy series was approximately 0.3% (10,11). Among patients with congenital heart disease, the prevalence of LSVC is much higher (12). Congenital heart malformations that show a high frequency of persistent LSVC are tetralogy of Fallot (11%), atrioventricular septal defects (19%), mitral atresia (17%) (13), and juxtaposition of the right atrial appendage (RAA) (34%) (14). Whereas persistent LSVC

Figure 36.7. Venogram of a 4-month-old girl with absent RSVC and persistent LSVC draining into the coronary sinus (CoS) and right atrium.

to coronary sinus results in normal return of systemic venous blood to the RA, this anomaly may have clinical implications for patients with associated cardiac malformations.

Anatomy

The size of the LSVC varies. It may be smaller than, equal to, or larger than the size of the RSVC. An LIV of variable size may be present in 60% of cases (15). The LSVC starts at the junction of the left jugular and left subclavian veins. It descends in front of the aortic arch and the left pulmonary vessels and, after receiving the left superior intercostal vein, it penetrates the pericardium. It then proceeds obliquely along the posterior wall of the LA and joins the coronary sinus in the posterior left atrioventricular groove (5,10). The flow of the LSVC blood into the coronary sinus results in its enlargement and posterior displacement of its orifice on the floor of the RA (Figs. 36.7 and 36.8). The thebesian valve seldom, if ever, is present.

Clinical Manifestations

When the LSVC drains into the RA through the coronary sinus, physiology is normal and there are no clinical manifestations. When this anomaly accompanies other congenital cardiac malformations, it may pose diagnostic and technical difficulties during catheterization and cardiac surgery (16). Enlargement of the coronary sinus resulting from a persistent LSVC may interfere with blood flow from the LA into the left ventricle. An increase in the magnitude of the left-to-right shunt at the atrial level was found in patients with secundum atrial septal defects (ASDs), persistent LSVC, and dilated coronary sinus (17,18).

Diagnostic Features

The presence of an LSVC can be suspected on a chest radiogram based on a shadow along the left upper border of the mediastinum. Echocardiography is the most widely used non-invasive method to detect an LSVC (19). Huhta et al. (20), before color Doppler became available, demonstrated that detection of LSVC by 2-D echocardiography had a specificity of 100% and a sensitivity of 96%.

Imaging of a dilated coronary sinus is often the first clue to the diagnosis of an LSVC during the course of an echocardiographic examination. The coronary sinus can be imaged from the subcostal, apical, and parasternal windows (Fig. 36.9). It appears as a tubular structure in the posterior left atrioventricular groove with an opening into the postero-inferior aspect of the RA adjacent to the orifice of the IVC. The LSVC and its drainage into the coronary sinus can be imaged from the subcostal short-axis view in patients with adequate acoustic windows. In most patients, the LSVC can be imaged from the suprasternal notch or from the high left parasternal/subclavicular windows (Fig. 36.9D). From these windows, the presence and size of the LIV can be imaged. In general, there is an inverse relationship between the caliber of the LSVC and the LIV. Pulsed and color Doppler flow mapping are useful in demonstrating typical systemic venous flow patterns in the LSVC. Flow mapping by Doppler also is important in differentiating between an LSVC and other veins that may connect with the LIV. These include partial or total anomalous pulmonary venous connection, a left superior intercostal vein, and a levoatrialcardinal vein (LACV). In contrast to an LSVC to an intact coronary sinus, however, the direction of blood flow in these veins is expected to be into the LIV.

Figure 36.8 Persistent left superior vena cava (LSVC). **A:** LSVC drains via coronary sinus (CS) into right atrium (RA). The diameters of the LSVC and the left innominate vein (L. Inn. V.) vary inversely; the latter may be absent. **B:** Absence of the right superior vena cava. **C:** Bilateral superior venae cavae associated with unroofed coronary sinus and drainage of LSVC into left atrium (LA); the right atrial orifice of the coronary sinus is enlarged and allows an interatrial communication. An anomalously connecting pulmonary vein can be diagnosed by following the vein into the lung hilum, by the Doppler flow pattern, and by the absence of normal connection of the involved pulmonary vein to the LA. The left superior intercostal vein is a small systemic vein that can be followed toward the anterior chest wall. An LACV is a remnant of an early embryonic venous channel that connects the splanchnic plexus of the lungs with the cardinal system. In the mature heart, it connects the LA or a pulmonary vein with the left innominate or other systemic veins (Fig. 36.10). Typically, it is associated with severe left atrial outlet obstruction, such as mitral stenosis or atresia with a restrictive patent foramen ovale or an intact atrial septum, and provides an alternative egress for pulmonary venous blood (21). The diagnosis can be established by following the anomalous vein from its origin (either from the LA or from one of the pulmonary veins) to its termination in a systemic vein. Unlike persistent LSVC that

courses anterior to the left pulmonary artery (LPA), an LACV typically ascends posterior to it (22). The different positions of an LSVC and an LACV in relation to the LPA are important for distinguishing between these venous structures. Although in some patients the levoatrialcardinal vein can be ligated safely or closed in the catheterization laboratory, inadvertent obstruction to venous drainage from the left lung can occur. Demonstration of retrograde flow in an LSVC toward the LIV indicates that the LSVC is venting obstructed coronary sinus flow, usually owing to stenosis or atresia of the coronary sinus orifice.

Persistent LSVC can be diagnosed by magnetic resonance imaging (MRI) either by spin echo or by gradient echo sequences. Magnetic resonance angiography (MRA) is particularly suitable for rapid noninvasive delineation of systemic venous anatomy (Fig. 36.10). By cardiac catheterization, LSVC can be suspected by the presence of

Figure 36.10. Three-dimensional magnetic resonance angiogram of a levoatriocardinal vein (LACV) in an asymptomatic 13-year-old boy with mild pulmonary valve stenosis and single right coronary artery. **A:** The levoatriocardinal vein is seen as a venous channel between the left upper pulmonary vein and the left innominate vein (LIV). The dilated left innominate vein is joined by the right innominate vein (RIV) to form the superior vena cava (SVC), which drains into the right atrium (RA). **B:** The connection of the left upper pulmonary vein (LUPV) with the levoatriocardinal vein (LACV) and with the left atrium (LA). Ao, aorta; LV, left ventricle; RLPV, right lower pulmonary vein.

higher-than-expected coronary sinus oxygen saturation. LIV angiography with balloon occlusion proximal to the injection site is diagnostic. The LSVC can be approached either through the right SVC (when the innominate vein is present) or through the coronary sinus (Fig. 36.7). The diagnosis of systemic venous anomalies can be established reliably by echocardiography and MRI. Cardiac catheterization is unnecessary in most patients.

Treatment

No treatment is necessary for an isolated LSVC to an intact coronary sinus.

Bilateral Superior Venae Cavae with an Unroofed Coronary Sinus

Anatomy

Partial or complete absence of the common wall between the LA and the coronary sinus has been termed partial or complete unroofing of the coronary sinus. In hearts with partial or complete unroofing of the coronary sinus, a persistent LSVC drains into the LA. In patients with a normal septum primum and septum secundum, the orifice of the unroofed coronary sinus will function as an interatrial communication. This type of interatrial communication has been erroneously diagnosed as a posterior ASD occurring in association with a persistent LSVC and unroofed coronary sinus (23).

Bilateral SVC with an unroofed coronary sinus may occur in association with other congenital heart defects and rarely as an isolated lesion (24). Visceral heterotaxy with asplenia exhibits the highest incidence of bilateral SVCs with a completely unroofed coronary sinus. In a study of

58 postmortem cases of visceral heterotaxy with asplenia, the incidence was 67%, and in 46 postmortem cases of polysplenia, the incidence was 13% (1). The reason for the high frequency of an unroofed coronary sinus in asplenia is not known. The high frequency of bilateral SVCs in asplenia probably represents a remnant of the normal early embryonic symmetry of the systemic veins that is characteristic of visceral heterotaxy.

As mentioned, a persistent LSVC entering the LA when the coronary sinus is unroofed should be distinguished from persistence of an embryonic connection between the LA and a systemic vein (LACV) or between the left pulmonary veins and a systemic vein (vertical vein) (25). Almost all cases of LACV have been associated with severe left atrial outlet stenosis or atresia (21). Rarely, a normally connected left upper pulmonary vein to the LA may maintain the early embryonic connection with the LIV without left atrial outflow stenosis or atresia (21). We also encountered such a case (Fig. 36.10). It is interesting to note that both cases had coarctation of the aorta.

Clinical Manifestations

Most patients with an isolated persistent LSVC to a partially or completely unroofed coronary sinus also have a large coronary sinus ostium that functions as an interatrial communication (Raghib syndrome) (Fig. 36.8C). The hemodynamic consequences of the Raghib syndrome are cyanosis and left-to-right shunting through the “ASD.” Systemic arterial desaturation is caused by mixing of LSVC blood with pulmonary venous blood in the LA. The degree of arterial desaturation is related to the net right-to-left shunt, which, in turn, depends on the amount of systemic venous blood carried by the LSVC and the proportion of systemic venous blood that crosses the atrial septum and reaches the pulmonary circulation. In most

patients, the arterial oxygen saturation ranges between 85% and 95%. These patients exhibit varying degrees of cyanosis, clubbing of the nail beds, and polycythemia. They are at risk for complications of right-to-left shunting, including paradoxical emboli, brain abscess, strokes, and death. In some patients, the coronary sinus ostium is atretic and there is no significant interatrial communication. The only clinical manifestations in these patients are cyanosis and its sequelae. Patients with a significant interatrial communication exhibit signs and symptoms related to left-to-right shunting as well as cyanosis. When a persistent LSVC to an unroofed coronary sinus is associated with complex congenital heart disease (often in the context of heterotaxy syndrome), the clinical features of LSVC drainage to the LA are obscured by manifestations of the associated anomalies. When right atrial outflow stenosis or atresia coexists with a persistent LSVC to an unroofed coronary sinus, the shunt is exclusively from right to left.

Diagnostic Features

The LSVC may appear as a shadow along the left upper border of the mediastinum on the chest radiogram. The electrocardiographic features of isolated LSVC to an unroofed coronary sinus are similar to those in patients with uncomplicated secundum ASD. The frontal axis of the P wave may be abnormal in patients with heterotaxy syndrome, reflecting a left sinoatrial node or an ectopic atrial rhythm.

Echocardiography is the definitive imaging modality in most patients (26). The LSVC and its drainage into the LA can be imaged from the subcostal window in young patients and from the precordial and suprasternal notch windows in most patients. The posterior left atrioventricular groove is examined in detail to ascertain the extent of deficiency of the coronary sinus septum. When the coronary sinus septum is completely unroofed, the LSVC terminates in the upper left posterior corner of the LA between the left upper pulmonary vein posteriorly and the left atrial appendage anteriorly. Flow mapping with color Doppler is useful in demonstrating flow from the LSVC into the LA. If the diagnosis is still in doubt, a contrast injection in a left arm vein establishes the diagnosis by demonstration of microbubbles in the LA before they appear in the RA. MRI is increasingly used to establish the diagnosis, especially when technical limitations compromise the quality of echocardiography or when the anatomy has not been completely delineated. By cardiac catheterization, the diagnosis is established by demonstration of a step-down in oxygen saturation between the pulmonary veins and the LA and by LSVC-selective angiocardiography (Fig. 36.11).

Treatment

The coronary sinus defect of a partially or completely unroofed coronary sinus that receives an LSVC must be repaired to avoid complications of cyanosis and its sequelae and of chronic left-to-right shunting. Accurate preoperative diagnosis is essential to avoid inadvertent closure of an enlarged coronary sinus orifice that is mistaken for a secundum ASD. Such an error will result in significant postoperative cyanosis.

If the LSVC is relatively small and there is an adequate-sized LIV, the LSVC can be ligated and the interatrial communication closed, leaving the coronary sinus blood to drain into the LA. In the absence of an adequate-sized bridging LIV, the coronary sinus is “reroofed” (27). This is achieved by baffling the LSVC along the posterior wall of the LA into the RA. Care is taken to avoid the orifices of the pulmonary veins. A coronary sinus defect also can be closed in the catheterization laboratory with an ASD device.

Figure 36.11. Venogram of a left superior vena cava (LSVC) entering the left side of a common atrium via an unroofed coronary sinus in a 15-month-old boy with visceral heterotaxy. A catheter inserted into the right femoral vein entered a left venous channel that crossed the diaphragm and entered the left side of a common atrium. LA, left atrium. The additional venous anomalies of this case are presented in Figure 36.20. (The angiocardiogram of this patient was kindly provided by Dr. John Murphy, duPont Hospital for Children, Wilmington, DE.)

Absent Right Superior Vena Cava in Visceroatrial Situs Solitus

Anatomy

Absent or atretic right SVC in viscerotaxial situs solitus is rare, occurring in 0.07% to 0.13% of patients with cardiovascular malformations (28,29). In a study of 121 cases, we found that this anomaly occurred both in patients with structurally normal hearts (54%) and in patients with congenital heart defects (46%) (30). This anomaly is characterized by persistence of the LSVC draining to the RA via the coronary sinus and by left-sided azygos vein draining into the LSVC (Fig. 36.8B). Less constant features were additional cardiovascular malformations (46%) and rhythm abnormalities (35%) that usually appeared related to complications of old age. In seven cases (6%), the coronary sinus was unroofed; hence, the LSVC drained into the LA (30). The LSVC, in cases of atretic or absent right SVC, should not be considered an inverted SVC. The origin and course of this LSVC are exactly the same as the origin and course of the LSVC, which may be present when the right SVC is normal (30).

Clinical Manifestations

In the absence of additional cardiovascular malformations, absence of the right SVC with drainage of the LSVC into the RA via the coronary sinus is asymptomatic. Of the 121 cases reviewed by Bartram et al. (30), 36 (30%) had no associated anomalies, and the systemic venous anomaly was an incidental finding. Rhythm disturbances without additional structural heart disease were reported in 29 patients (24%), including atrioventricular block, sinoatrial node dysfunction, ventricular tachycardia, left and right bundle-branch block,

supraventricular tachycardia, and sudden death. A range of associated cardiovascular malformations with or without arrhythmia were found in 56 patients (46%). When the only associated cardiac anomaly is partial or complete unroofing of the coronary sinus (found in four patients), cyanosis dominates the clinical picture.

Diagnostic Features

The clinical relevance of establishing the diagnosis of absent right SVC with a persistent LSVC to the coronary sinus in viscerotransposition is mainly to avoid difficulties during the following procedures: transvenous pacemaker implantation, venous cannulation for cardiopulmonary bypass or extracorporeal membrane oxygenator, and placement of a right ventricular or pulmonary arterial monitoring line through the subclavian or jugular veins. Precise preoperative knowledge of the systemic venous anatomy is also crucial before surgery that includes cavopulmonary anastomosis and orthotopic heart transplantation. The diagnosis can be established by echocardiography, MRI, CT, or angiography (Fig. 36.12).

Treatment

No intervention is indicated when the physiology is normal.

Left Atrial or Biatrial Drainage of Right Superior Vena Cava

Anatomy

Left atrial drainage of the RSVC is a rare malformation that typically manifests itself as unexplained cyanosis and clubbing in patients who do not have any other signs of a heart defect (31). A variation of this malformation is an RSVC draining into both atria (32). Van Praagh et al. (31) recently reported two cases of biatrial drainage of the RSVC and one case of left atrial drainage of the RSVC and reviewed 26 previously published cases. Nutzel described the earliest reported cases of biatrial

drainage of the RSVC in a 47-year-old man (reference 18 in Van Praagh et al. [31]). The earliest reported case in the English literature of left atrial drainage of the RSVC involved a 10-year-old girl described by Wood (33). At least 18 additional cases have been published in English since then (31,34); 10 of these patients underwent surgery, and in all but one, the right upper lobe pulmonary veins usually drained into the RSVC (35). A persistent left SVC was present in three cases (31,35,36). In several of the operated cases, the diagnosis of pulmonary veins draining into the RSVC was missed preoperatively.

Based on our understanding of the nature of sinus venosus defects (31,37), we believe this malformation represents a sinus venosus defect of the SVC type in association with atresia of the RSVC orifice (Fig. 36.13). A sinus venosus defect of the SVC type results from the deficiency of the common wall between the SVC and the right upper pulmonary vein (RUPV) (37). This defect unroofs the RUPV and its branches into the RSVC. The unroofed RUPV then drains into the SVC, and its left atrial orifice becomes the interatrial communication. This interatrial communication is not a defect; like the right atrial orifice of an unroofed coronary sinus, it functions as an interatrial communication but is not an ASD. Depending on the pressure and compliance differences between the two atria, left atrial blood can be shunted into the SVC–right atrial junction, or RSVC blood can enter the LA. We suspect that if the RSVC-to-LA shunt predominates during early fetal life, the blood flow toward the RA through the right atrial orifice of the SVC will be diminished or completely eliminated. Lack of blood flow will result in gradual involution of the proximal segment of the SVC and stenosis or atresia of its orifice. In cases of stenosis of the SVC orifice, the SVC will drain into both atria (31,32), whereas in cases of SVC orifice atresia, the SVC will drain only into the LA (Fig. 36.14) (31). The true nature of the interatrial communication was fully understood by Hackensellner (38), who reported the postmortem findings in a 72-year-old man with biatrial drainage of the RSVC. A similar view was expressed by Shapiro et al. (32), who also realized that if the shunt from the RSVC to the LA was large

Figure 36.12. Venogram of the innominate vein (Innom V) in a patient with absence of the right superior vena cava and persistence of the left superior vena cava (LSVC), which drains into the right atrium via the coronary sinus (CoS).

Figure 36.13. Diagrammatic representation of the anatomy of right superior vena cava (SVC) drainage into left atrium (LA). A combination of sinus venosus defect and atresia of the right atrial orifice of the superior vena cava results in drainage of the right upper pulmonary vein and SVC into the left atrium via the left atrial orifice of the right upper pulmonary vein (see text for details). IVC, inferior vena cava; MV, mitral valve; RA, right atrium; S1, septum primum; S2, septum secundum; TV, tricuspid valve.

Figure 36.14. Drainage of right superior vena cava (RSVC) to left atrium (LA). **A:** Right atrial angiogram showing catheter course from the inferior vena cava (IVC) to the right atrium (RA). The contrast fills the RA and right atrial appendage (RAA) but not the superior vena cava. **B:** The catheter crosses the foramen ovale to the left atrium (LA) and is advanced into the RSVC. The RSVC-to-LA drainage is seen with contrast entering the RA through the foramen ovale. **C:** Drainage of the right upper pulmonary vein (RUPV) into the RSVC is seen on a later frame. **D:** Echocardiogram from the subcostal short-axis view showing the RSVC-to-LA drainage. NG, nasogastric.

enough, “the normal SVC channel to the RA became relatively hypoplastic.” We had reached the same conclusion prior to our knowledge of these two reports.

Clinical Manifestations

Cyanosis is the dominant clinical feature in patients with drainage of the RSVC to the LA. The degree of cyanosis may be mild, and symptoms may not develop until late childhood or adolescence (31,39) and rarely until adulthood (40). The risks of polycythemia, shortness of breath, decreased exercise tolerance, systemic emboli, brain abscess, and other cerebrovascular complications increase with age. The echocardiogram or

angiocardiogram of such patients shows a common entrance site of the RSVC and the RUPV in the roof of the LA (36).

Treatment

The RSVC flow is surgically diverted into the RA. In the past, this was done by creating an ASD and redirecting SVC flow into the RA and the pulmonary blood flow into the LA (41). More recently, the preferred surgical approach has involved transection of the RSVC above the entrance of the RUPV(s) and anastomosis of the transected caval end to the RAA (31). A surgical technique without the use of cardiopulmonary bypass was reported by Nazem and Sell (42).

Figure 36.15. Retroaortic innominate vein.

RSVC, right superior vena cava. **B:** Gadolinium-enhanced magnetic resonance angiogram showing a retroaortic innominate vein. Ao, aorta; LA, left atrium; RA, right atrium; RPA, right pulmonary artery.

Retroaortic Innominate Vein

Anatomy

Retroaortic innominate vein (RAIV), also known as postaortic innominate vein, is a rare systemic venous anomaly characterized by an abnormal position of the LIV behind the ascending aorta (Fig. 36.15). The normal course of the LIV is from left to right, anterior to the aortic arch in the superior mediastinum. It then joins the RIV to form the RSVC. In RAIV, the confluence of the left subclavian and left common jugular veins forms the LIV, which then turns inferiorly to run a course that

is initially similar to that of a persistent LSVC. After passing anterior to the LPA and before reaching the LA, the LIV turns rightward and courses horizontally behind the ascending aorta to reach the SVC below the insertion of the azygos vein (Fig. 36.15). The insertion of the RAIV into the SVC is only a short distance above the SVC–RA junction. We encountered a heart specimen in which the RAIV also communicated with an LSVC that drained into a partially unroofed coronary sinus. Another rare anatomic variation is *duplication of the left innominate vein*—defined as the coexistence of a retroaortic LIV and a normally positioned LIV (Fig. 36.16).

Figure 36.16. Duplication of the left innominate vein. Anterior (**A**) and posterior (**B**) views of volume reconstruction of gadolinium-enhanced 3-D magnetic resonance angiogram. The anterior (normal position) and posterior (retroaortic; *arrow*) left innominate veins form a ring that encircles the aorta.

This rare anomaly was first reported in 1888 (43), and 62 cases have been reported to date. Choi et al. (44) reported 24 patients with RAIV among 2,457 patients with congenital heart disease (0.98%). Of the 35,000 persons who underwent an echocardiographic examination at Children's Hospital in Boston from 1980 through 1997, 31 patients were diagnosed with RAIV (0.09%). Most patients with RAIV have associated congenital cardiac malformations, including tetralogy of Fallot with or without pulmonary atresia, truncus arteriosus, atrioventricular septal defect, heterotaxy syndrome, hypoplastic left heart syndrome, pulmonary atresia with intact ventricular septum, coarctation of the aorta, and others (44–46). In some patients, RAIV is an incidental finding not associated with other congenital cardiac anomalies. Based on autopsy findings, Gerlis and Ho (46) and Kitamura et al. (47) distinguished between RAIV that courses ventral to or dorsal to the ligamentum arteriosum. This distinction, however, cannot be made in living patients unless the ductus arteriosus is patent. The cause and embryogenesis of RAIV are unknown. Gerlis and Ho (46) suggested that the anomaly results from failure of the high transverse capillary plexus that forms the LIV to develop at a time when the lower portion of the left anterior cardinal vein atrophies. In such circumstance, venous blood returning from the left side of the head and the left arm may drain through a lower venous plexus that communicates between the left and right anterior cardinal veins. This lower venous plexus then forms the RAIV.

Clinical Manifestations

RAIV is widely considered an anatomic variant without clinical ramifications. In 3 of the 31 patients with RAIV diagnosed at Children's Hospital in Boston, the anomaly was associated with defects that required a cavopulmonary anastomosis as part of their surgical repair. The abnormal connection of the RAIV to the SVC at or below the level of the right pulmonary artery hindered the surgical mobilization of the SVC and necessitated modifications of the surgical technique.

Diagnostic Features

The anomaly can be identified readily by echocardiography, angiocardiology, and MRI (Figs. 36.15B and 36.16). Accurate echocardiographic diagnosis is based on tracking the LIV

from its origin through its retroaortic course to the SVC (45). The imager must be careful not to confuse a RAIV with a persistent LSVC. The latter will connect with the coronary sinus or with the LA if the coronary sinus is unroofed. Cine MRI and 3-D MRA are particularly useful in depicting the anatomy.

Treatment

No treatment is necessary because blood flow is normal.

ANOMALIES OF THE CORONARY SINUS

Coronary Sinus Defect and Unroofed Coronary Sinus

Anatomy

Unroofed coronary sinus almost always is associated with a persistent LSVC. This condition was discussed earlier in this chapter. A coronary sinus defect without an associated LSVC is rare, and the physiology is the same as in ASD. The interatrial communication, however, is through the mouth of the coronary sinus, which is located below and posterior to the fossa ovale. It also has been observed in patients with isolated secundum ASD (48). When unroofing of the coronary sinus occurs in cases with an intact atrial septum, its orifice takes the form and function of an interatrial communication (Fig. 36.8C). When unroofed coronary sinus is associated with an ostium primum defect, a complete common atrioventricular septal defect, or a common atrium, the orifice of the coronary sinus merges with the atrial septal deficiency and becomes unrecognizable. In some patients, the coronary sinus ostium is atretic and the coronary sinus defect is the only egress for coronary venous blood (Fig. 36.17A). A coronary sinus defect also may be an alternate or an accessory route for blood flow from an atrium that has no other functional outlet (Fig. 36.17C).

A left or a right hepatic vein may drain separately from the other hepatic veins into the coronary sinus (49). When the orifice of the coronary sinus is enlarged as a result of a persistent LSVC, it may incorporate into its territory the orifice of the IVC. In a recently reported case of absent RSVC and persistent LSVC, the entire systemic venous return entered the heart by way of the coronary sinus orifice (50).

Figure 36.17. Anomalies of the coronary sinus. Atrisia of the ostium of the coronary sinus (CS). **A:** Drainage of coronary sinus blood into the left atrium (LA) through a coronary sinus septal defect. **B:** Drainage of coronary sinus blood in a retrograde direction into a persistent left superior vena cava (LSVC), to left innominate vein (L. Inn. V.), and to right atrium (RA). **C:** Coronary sinus septal defect associated with a persistent LSVC (Raghib syndrome). Card. V., cardiac vein; IVC, inferior vena cava; RSVC, right superior vena cava.

Clinical Manifestations

The clinical manifestations of an unroofed coronary sinus associated with a persistent LSVC were discussed earlier in this chapter. Patients with partial or complete unroofing of the coronary sinus without an LSVC exhibit signs and symptoms identical to those with a secundum ASD.

Diagnostic Features

Echocardiographic diagnosis can be made by imaging the coronary sinus septum in the posterior left atrioventricular groove. Color Doppler flow mapping is useful in demonstrating blood flow through a defect identified by 2-D imaging. In the presence of an associated LSVC, left-arm contrast injection will result in the appearance of bubbles in the LA before they appear in the RA. In the absence of an associated LSVC, contrast injection can aid only in demonstrating the atrial-level shunt. Surgery is usually performed for associated malformations.

Coronary Sinus Orifice Atresia

Anatomy

Atresia or severe stenosis of the right atrial orifice of the coronary sinus is rare (51). The coronary sinus is usually well formed, and the orifice is covered by a thin membrane-like tissue that appears to be related to the thebesian valve. In 13 of the 15 heart specimens described by Lucas and Krabill (52), an alternative exit for coronary venous blood return was identified. A small LSVC was found in six cases, a large thebesian vein in five, a coronary sinus septal defect in one, and a connection with the IVC in one case. No alternative outlet for coronary sinus blood flow was identified in the remaining two heart specimens. In 12 of the 15 cases, associated congenital cardiac anomalies were found.

Clinical Manifestations

Myocardial ischemia is unlikely as long as there is an alternate egress for the coronary sinus blood. Myocardial ischemia, infarction, and death have been reported in several patients in whom there was no alternative exit for the coronary sinus blood. Two patients with coronary sinus orifice atresia died of myocardial ischemia following ligation of a small LSVC (52,53). Two neonates without anatomic evidence of an egress route for the coronary sinus blood died at 6 and 10 days, respectively. Both had myocardial hemorrhage and necrosis at autopsy.

Diagnostic Features

The demonstration of a persistent LSVC to an intact coronary sinus with retrograde flow toward the innominate vein should prompt a careful examination of the coronary sinus ostium. Angiographic demonstration of retrograde flow in the coronary sinus and a small-caliber LSVC is suggestive of the diagnosis (Fig. 36.18) (51,54).

Coronary Sinus Aneurysm or Diverticulum

Anatomy

Congenital diverticulum of the coronary sinus was first described in 1983 by Ho et al. (55) in a 1-year-old child by angiography and in a 23-year-old man with tachycardia and sudden death. Gerlis et al. (56) described two patients who died of malignant arrhythmia associated with posteroseptal accessory atrioventricular pathways. Each had a coronary sinus aneurysm.

Figure 36.18. Coronary sinus orifice atresia. Selective balloon occlusion angiogram in the left innominate vein (LIV) in an 8-year-old girl with mitral atresia and a large left ventricle. Contrast material fills the innominate vein, left superior vena cava (LSVC), part of the coronary sinus (CoS), and two large cardiac veins (CV). Blood flows in a retrograde direction from the coronary sinus to the LSVC, to the left innominate vein, to the right superior vena cava (RSVC), and, finally, into the right atrium. (Reprinted from Shinpo H, Van Praagh S, Parness I, et al. Mitral atresia with a large left ventricle and an underdeveloped or absent right ventricular sinus: clinical profile, anatomic data and surgical considerations. *J Am Coll Cardiol* 1992;19: 1561–1576, with permission from Elsevier.)

Guiraundon et al. (57) described the entity of coronary sinus diverticulum associated with Wolff-Parkinson-White syndrome in a study of 65 patients with posteroseptal accessory pathways. Intraoperatively, six were found to have coronary sinus diverticula in the posteroseptal region. The coronary sinus diverticulum is a pouch with its neck originating in the coronary sinus proximal to the entrance of the middle cardiac vein. The pouch, 2 to 5 cm in diameter, extends into the left ventricular wall.

Similar coronary sinus diverticula or aneurysms have been observed in children without the presence of Wolff-Parkinson-White syndrome or tachycardia. One case of a 20-month-old girl (58) involved a fistulous connection between the coronary sinus and the left ventricle without any other cardiac defects. Di Segni et al. (59) described a coronary sinus diverticulum that penetrated the right ventricular posterior wall in a newborn with mitral atresia and hypoplastic left heart syndrome. Conduction studies indicated that the accessory pathway is closely associated with the diverticulum and that the conduction abnormality disappears only after separation or ablation of the coronary sinus diverticulum neck.

Diagnostic Features

Coronary sinus diverticulum has been diagnosed by echocardiography (58). The coronary sinus is first imaged from the subcostal, apical, and parasternal windows. The aneurysm is seen as an outpouch, typically with a distinct neck, which extends behind the left ventricle or into the ventricular myocardium. Color Doppler flow mapping is helpful in making the diagnosis and in delineating the connection into the aneurysm by displaying a jet from the coronary sinus (59). Other sites of

connection may be demonstrated with color Doppler. Many of the reported cases, however, have been defined during intra-cardiac electrophysiologic mapping and ablation of supraventricular tachycardia as well as during surgical dissection at the time of operative ablation of the accessory pathway (57).

Treatment

The six patients of Guiraundon et al. (57), four men and two women aged 19 to 67 years, all had surgical treatment of the diverticulum. They also had dissection of the posterior canal region. The coronary sinus was dissected away from the left ventricle and the arteriovenous junction and that site was cryoablated. No postoperative recurrences or complications occurred. The indication for intervention in cases with a coronary sinus aneurysm or diverticulum who do not have associated tachycardia is unclear.

ANOMALIES OF THE INFERIOR VENA CAVA

Interrupted Inferior Vena Cava

Anatomy

Absence of the hepatic segment of the IVC with azygos continuation into the right or left SVC is referred to as an interrupted IVC. In rare cases, the infrahepatic segment of the IVC may continue to both right and left SVC via bilateral azygos veins (Fig. 36.19). Interrupted IVC was reported as an incidental autopsy finding as early as 1793 (60). Although the presence of multiple spleens and abnormalities of the visceral situs were mentioned in the earliest reported cases (1,61–63), their relation to interrupted IVC was not appreciated. It was not until 1967 that Moller et al. (64), studying the anatomic data of 12 cases with visceral heterotaxy and polysplenia, concluded that interrupted IVC represents one of the characteristics of the polysplenia syndrome. Since then, many publications confirmed this association (65). In our study of 46 postmortem cases of visceral heterotaxy with polysplenia, the incidence of interrupted IVC was 86% (1). Although as a rule interrupted IVC occurs in patients with situs abnormalities and congenital heart defects, it also has been reported in patients with normal hearts (66,67) and rarely in patients with asplenia (68).

Clinical Manifestations

Because interrupted IVC with azygos continuation usually does not result in a physiologic abnormality, this venous abnormality does not result in clinical manifestations. Its clinical importance is due to its frequent association with the heterotaxy syndrome and polysplenia. Interrupted IVC with azygos continuation can complicate cardiac catheterization and interventional procedures such as radiofrequency catheter ablation. In patients whose associated cardiovascular anomalies require surgical therapy that involves redirection of the systemic venous return to the pulmonary arteries (bidirectional Glenn and modified Fontan procedures), awareness of the anomaly and appropriate surgical planning are important.

Diagnostic Features

Interruption of the IVC with azygos continuation to the SVC can be diagnosed readily by echocardiography (69,70). The diagnosis is based on imaging of the size, location, and course of the IVC and the azygos vein from the subcostal window. Normally, in the subcostal short-axis view, the renal-to-hepatic segment of the IVC is seen as an oval blood vessel located anterior and to the right of the abdominal aorta. The azygos vein is a much smaller vessel seen beside the vertebral bodies. In patients with heterotaxy syndrome, the IVC may be juxtaposed to the abdominal aorta either to the left or to the right of the spine (26,69). An intact IVC can be seen throughout most or all of its length from the subcostal parasagittal plane. When the renal-to-hepatic segment of the IVC is absent, no IVC is seen below the liver. Care must be taken not to confuse a hepatic vein with the IVC. The azygos vein is enlarged and can be followed cranially until its connection with a SVC (which may be right-sided, left-sided, or there may be bilateral azygos with connections to the left and right SVCs). The drainage of the azygos vein to the SVC also can be imaged from the parasternal and suprasternal windows.

An interrupted IVC with azygos continuation can be diagnosed readily by MRI. In particular, 3-D MRA is accurate and effective in delineating normal and abnormal systemic venous anatomy. During cardiac catheterization, venous angiography from the lower extremity is diagnostic.

Treatment

No specific treatment of an interrupted IVC with azygos continuation is indicated. Inadvertent ligation of the azygos vein can lead to death (66).

Figure 36.19. Posterior view of the heart, lungs, liver, and kidneys of a 6 1/2-month-old boy with visceral heterotaxy and left-sided polysplenia. There is interruption of the right-sided inferior vena cava (IVC) with bilateral azygos veins (Az V) connecting with bilateral superior venae cavae (RSVC, LSVC). The RSVC entered the right atrium directly. The LSVC continued into the coronary sinus, which drained normally into the right atrium. Ao, aorta; LRV, left renal vein; Ren, renal; RRV, right renal vein. (From Van Praagh S, Santini F, Sanders SPJ. Cardiac malpositions with special emphasis on visceral heterotaxy [asplenia and polysplenia syndromes]. In: Nadas AS, Fyler DC, eds. *Nadas' Pediatric Cardiology*. 4th ed. Philadelphia, PA: Hanley & Belfus, 1992: 589–608, with permission.)

Bilateral Inferior Venae Cavae

Anatomy

The bilateral nature of four of the five venous systems that contribute to the formation of the IVC can easily explain the presence of bilateral IVCs above and below the liver (Fig. 36.5). Bilateral suprahepatic IVCs (i.e., a normal IVC and a contralateral hepatic vein) are a frequent finding in cases of visceral heterotaxy with asplenia. In our study of 109 postmortem cases of visceral heterotaxy, bilateral suprahepatic IVC was present in 28% of the asplenia group and in 6% of the polysplenia group (1). Bilateral suprahepatic IVCs also can occur rarely in patients with normal visceral situs. The left-sided hepatic vein in those cases drains into a normal coronary sinus.

Bilateral infrarenal IVCs, in their entire length or in some of their segments, can occur in patients with normal or abnormal visceral situs and have been described in several reports (71). They do not produce any hemodynamic disturbance. The same is true for the suprahepatic duplication of the IVC if a normal coronary sinus is present.

The bilaterality of four of the five components of the IVC explains the cases where a left-sided IVC may become right-sided at the level of the liver and at its suprahepatic segment. Similarly, a right-sided IVC may become left-sided at the level of the liver and at its suprahepatic segment. The same is true in cases of interrupted IVC.

The existence of an unpaired segment of the IVC (the hepatic segment) does not permit the formation of truly complete bilateral IVC. Nevertheless, in rare cases of absent ductus venosus, it is possible to have two venous channels mimicking bilateral IVCs (Fig. 36.20). In the case described by Lucas and Krabill (52), the right-sided venous channel was the true IVC.

The left-sided venous channel is composed of the left umbilical vein, the left portal vein, and the left hepatic vein, which enter the LA through an unroofed coronary sinus (see section on anomalies of the ductus venosus).

Inferior Vena Cava Drainage to the Left Atrium

Anatomy

During fetal life, about half of the IVC blood that enters the RA is directed toward the LA with the help of two venous valves: the eustachian valve (which is part of the embryonic right venous valve) and the valve of the foramen ovale (i.e., septum primum). The eustachian valve usually involutes by the time of birth and is represented by a ridge a few millimeters high, located between the mouth of the IVC and the tricuspid valve orifice. In some cases, however, for unknown reasons, the eustachian valve may persist with little or no change from its fetal size and attachments. If the foramen ovale is patent or if there is an ostium secundum defect, the IVC blood will continue to drain into both atria. Contrast injected into the IVC will appear into the LA and may create the erroneous impression that the IVC is connected with the LA. This has occurred in several cases reported as "left atrial IVC". (52).

A left atrial IVC also was thought to occur in cases in which all the systemic and all the pulmonary veins drained into a left-sided atrium. Present-day understanding makes it clear that this atrium is a left-sided RA. We now understand that it is impossible for the right horn of the sinus venosus (i.e., the IVC and the SVC) to be incorporated fully into the morphologically left atrium. By contrast, it is not unusual in patients with visceral heterotaxy and absence of septum secundum, for

Figure 36.20. Anteroposterior venogram in a 15-month-old boy with visceral heterotaxy, asplenia, bilateral IVCs, bilateral SVCs, common atrium, common atrioventricular septal defect, d-transposed aorta, and pulmonary atresia. **A:** Frame showing the cardiac end of the systemic venous return from the lower part of the body. **B:** Frame showing the inferior part of the systemic veins. Contrast material injected into the right iliac vein filled two venous pathways. The right-sided pathway represents a right-sided inferior vena cava (RIVC), which receives the right hepatic vein (RHV) and then enters the right side of the common atrium. The left venous channel appears to represent a left-sided IVC (LIVC), which connects with the left hepatic vein (LHV) and then joins the RIVC and drains into the common atrium via a common orifice. The two venous pathways connect by way of an extracardiac venous sinus (EVS) just before their entry into the common atrium. We think this case represents a rare variation of the venous pathways observed in cases of visceral heterotaxy. The right renal vein drained into the RIVC, and the left renal vein drained into the LIVC (not shown). LCIV, left common iliac vein. (This angiogram was kindly provided by Dr. John Murphy, duPont Hospital for Children, Wilmington, DE.)

half or all of the pulmonary veins to drain into the morphologically right atrium, which may be right- or left-sided (72). These well-documented possibilities can explain the reported cases of left atrial IVC except for the case reported by Gardner and Cole in 1955 (73).

This case concerned a woman who “at the age of 4 years had pneumonia and was subsequently noticed to be cyanosed.” She had a succession of three miscarriages, but at the age of 24 years she gave birth to a full-term normal infant. “She led a comparatively active life until the age of 32 years. Then one day while stretching up to a high shelf she collapsed suddenly and died.” According to the report by Gardner and Cole, postmortem examination of the heart revealed a normal coronary sinus and an intact atrial septum. The IVC was thought to drain directly into the LA. If the postmortem findings were correct, this case would defy what is known about the development of the atria, the sinus venosus, and the systemic veins of the human heart. We thought that, if possible, it was essential to reexamine this heart specimen, and this became possible thanks to the kindness and cooperation of Dr. Gardner, now professor of pathology in Edinburgh, Scotland.

Reexamination of this heart specimen revealed that a large segment of the posterior wall of the RA was missing. Consequently, no remnant of the IVC itself connecting with the RA could be found. Nevertheless, a small eustachian valve (right venous valve remnant) and a left venous valve with multiple fenestrations were easily identified (Fig. 36.21). The posteroinferior wall of the LA was also missing as a result of a postmortem artifact that was produced when the heart was removed from the chest by the prosector. This incision was made too high, above the IVC, removing a portion of the posteroinferior walls of both the right and left atria (Fig. 36.21). The defect in the left atrial wall was approximated by a stitch postero-

inferiorly, which inadvertently changed this defect into an approximately circular orifice thought to represent the orifice of the IVC. On reexamination, however, it was noted that the margins of this putative left atrial IVC consisted not of thin venous tissue, consistent with the wall of the IVC. Instead, it consisted of the left atrial myocardium, 3 mm in thickness, that lay outside of an approximately 1-mm-thick layer of fibrous tissue representing the left atrial endocardium (Fig. 36.21). Examination of the pulmonary histology by Dr. Reid revealed “large size and increased density of the arteries and veins consistent with the presence of arteriovenous communications sufficiently big or numerous to produce the effect of arterial-to-venous shunting.” Hence the cyanosis of the patient was explained with the histologic findings of the lungs.

This extraordinary case quoted repeatedly in the literature of the last 44 years was the result of an unintended misinterpretation of the anatomic findings of a heart specimen not examined in situ but brought to Professor Gardner’s attention “as a Coroner’s autopsy.” According to Professor Gardner, “diagrams were made much later. They were of the heart only.” “You have to recognize,” he wrote to us, “that the diagnosis of an IVC anomaly was not made at the time of the autopsy but only after subsequent examination of the heart.” Hence, we can now conclude that there has not been a documented case of the IVC connecting directly with the LA. The present knowledge of the embryology and possible connections of the IVC remains unchallenged.

Clinical Manifestations

Partial or complete drainage of the IVC into the LA results in cyanosis. The clinical manifestations are the result of right-to-left shunting, including polycythemia, brain abscess, and paradoxical emboli.

Figure 36.21. A: Opened right atrium and right ventricle of a 32-year-old woman. There is a small remnant of the right venous valve (RVV) separating the eustachian valve and a multiperforated remnant of the left venous valve (LVV). Between these two venous valves is the entry of the transected inferior vena cava (IVC). B: The posterior view of the atria and part of the ventricles of the same heart. Part of the posterior wall of the right atrium (RA) and of the left atrium (LA) has been transected by the prosector during the removal of the heart from the thoracic cavity. Note the thickness of the transected posterior wall of the left atrium. RPVs, right pulmonary veins. (These photographs were obtained with the kind permission of Professor D. L. Gardner.)

Figure 36.22. Echocardiogram in a 7-year-old boy with cyanosis. **A:** Subcostal short-axis image showing drainage of the inferior vena cava (IVC) to the left atrium (LA). **B:** Color Doppler flow mapping confirms flow from the inferior vena cava (IVC) to the left atrium (LA) and from the superior vena cava (SVC) to the right atrium (RA). At surgery, the atrial septum was resected, and an autologous pericardial patch was placed to the left of the inferior vena cava, thus incorporating it into the right atrium.

Diagnosis

The diagnosis can be established by echocardiography (Fig. 36.22), cardiac MRI, computed tomography, or cardiac catheterization.

Treatment

IVC blood is surgically redirected into the RA (74,75).

ANOMALIES OF THE DUCTUS VENOSUS

Anomalous Termination of the Umbilical Veins and Absent Ductus Venosus

Anatomic descriptions of abnormal termination of umbilical veins with absence of ductus venosus are rare. Recently, abnormal termination of umbilical veins and absence of ductus venosus were recognized clinically during umbilical vein cannulation of the newborn, during cardiac catheterization and angiography, during fetal or postnatal echocardiography, and at operation. Many of these clinical observations have been confirmed at autopsy. Usually, the absence of the ductus venosus and abnormal termination of the umbilical veins do not produce symptoms; however, two cases of intrauterine obstruction of the umbilical vein flow and three patients who required operation for postnatal intestinal obstructions secondary to the anomalous termination of the umbilical veins have been reported (76–80). The major clinical importance of these anomalies is the need to recognize them during prenatal and postnatal diagnostic studies and at the time of cannulation or catheterization of the umbilical vein in sick neonates.

Anatomy

Lucas and Krabill (52) reported autopsy findings of four specimens in the Jesse Edwards Registry of Cardiovascular

Pathology as well as 18 cases reviewed in the literature. The ductus venosus was confirmed to be absent in 18 of these 23 cases and presumed to be absent in the remainder.

The left umbilical vein persisted in five patients, terminating directly into the coronary sinus in one (Fig. 36.23A), into the coronary sinus by way of the left portal vein in two patients (Fig. 36.23B), and into the iliac vein in two. In our case shown in Figure 36.20, the left umbilical vein connected with the left common iliac vein. The right umbilical vein persisted in 11 patients and terminated directly into the RA in five (Fig. 36.23C), into the IVC in two (Fig. 36.23D), into the right portal vein in two, and into the RSVC in one.

Both the right and left umbilical veins persisted in three patients. In the first, the umbilical veins entered the right and left iliac veins, respectively; in the second, into the right and left portal veins, respectively; and in the third, the right umbilical vein entered the RA, and the left umbilical vein entered the left portal vein.

In four patients, the persisting umbilical vein could not be identified as either right or left. In three of these, the umbilical vein terminated into a right or left iliac vein, and in the fourth it communicated with the portal vein.

Clinical Manifestations

Of the 23 collected cases, 10 patients were male, 10 were female, and in 3 the gender was unknown or ambiguous. Only four patients had clinical evidence of abnormal physiology as a result of the abnormal termination of the umbilical vein; one had anatomic evidence of severe intrauterine obstruction of umbilical vein flow (77). Intestinal obstruction requiring surgical intervention was present as a result of the anomalous termination of the umbilical vein in three patients (78–80). These were females of ages 13 days, 27 years, and 31 years at the time of operation.

The number of umbilical arteries was identified in 16 patients; one umbilical artery was present in nine patients, two in the remainder. Thirteen of the twenty-three patients had

Figure 36.23. Diagram of absent ductus venosus and anomalous termination of an umbilical vein. **A:** Left umbilical vein (L. Umb. V.) terminates in coronary sinus (Cor. Sin.). **B:** Left umbilical vein (LUV) connects to left portal vein (LPV) and then continues to termination in coronary sinus. **C:** right umbilical vein (RUV) terminates in right atrium (RA). **D:** Right umbilical vein (R. Umb. V.) terminates in inferior vena cava (IVC). (LA, left atrium; LHV, left hepatic vein; LPV, left portal veins; PV, portal veins; RHV, right hepatic vein; RPV, right portal veins; SMV, superior mesenteric vein; SV, splenic vein; SVC, superior vena cava.)

no additional cardiac anomalies. Of the 10 patients with associated cardiac anomalies, two had tetralogy of Fallot, two had ectopia cordis, two had total anomalous pulmonary venous connections, and one each atrioventricular canal defect, mitral valve atresia, parachute mitral valve, and hypertrophic cardiomyopathy.

Diagnostic Features

Definitive anatomic diagnosis was accomplished by the following methods: catheterization of the umbilical vein, dye injection plus local surgical dissection of the umbilical vein, car-

diac catheterization, cardiac catheterization plus angiography, prenatal echocardiography, postnatal echocardiography, and at the time of operation for intestinal obstruction.

The major clinical importance of these cases is the potential for confusion and misinterpretation during catheterization of the umbilical vein in the neonate or abnormal course of the catheter in newborns undergoing cardiac catheterization by way of the umbilical vein; however, the increasing use of fetal echocardiography as well as echocardiography early in the postnatal period makes the noninvasive recognition of these anomalies of termination of the umbilical veins possible.

Postnatal Persistence of the Ductus Venosus

Horiguchi et al. (81) reported four cases of intrahepatic portosystemic shunt and reviewed six other cases from the literature.

Anatomy

These cases may have been congenital postnatal persistence of the ductus venosus because the shunt was away from the portal venous septum proximally to the distal hepatic veins or IVC distally. These intrahepatic portosystemic shunts are due to abnormal persistence of elements of the omphalomesenteric system (Fig. 36.4).

Clinical Manifestations

Three of the ten cases reported (82) resulted in portal-systemic encephalopathy. Hepatic function and liver histology were normal in some patients.

Diagnosis

Ultrasound or computed tomography delineated the diagnosis in most cases by demonstrating a large tortuous vessel originating from the portal vein that connected to the hepatic vein or IVC (82,83).

Treatment

We are not aware of successful treatment of the abnormality. In the absence of encephalopathy, treatment may not be indicated. If ligation of the ductus venosus is contemplated, one should establish the integrity of the portal system. If it is not intact, ligation could lead to mesenteric venous congestion and ultimately bowel ischemia.

PERSISTENT VALVES OF THE SINUS VENOSUS

This section is based on the excellent description of Lucas and Krabill (52). In the normal heart, remnants of the valves of the sinus venosus are the eustachian and thebesian valves and crista terminalis. Minor abnormal persistence of the valves of the sinus venosus results in larger-than-usual eustachian and thebesian valves and in Chiari networks. The latter are fine, filamentous structures that may represent persistence of either the right or left valves. Usually, Chiari networks are persistent right valves and extend from the crista terminalis to eustachian or thebesian valves. Networks derived from the left valves are inconspicuously located at the posterior rim of the limbus fossa ovalis and on the medial wall of the IVC as it enters the RA. None of these is of hemodynamic consequence.

In past years, pathologic persistence of the right valve of the sinus venosus was an anatomic phenomenon occasionally observed at autopsy. Recent developments in noninvasive imaging have resulted in clinical recognition of numerous instances of persistence of the right valve of the sinus venosus.

At one point in embryologic development, the right valve of the sinus venosus almost completely divides the RA into the sinus venosus portion and the muscular portion, and so abnormal persistence of the right valve may result in obstruction of blood flow into the RA or through the RA.

Cardiac anomalies attributable to maldevelopment of the right valve of the sinus venosus have been identified by various terms, including cor triatriatum dextrum, right atrial flap, right atrial spinnaker, right atrial sail, right atrial windsock, persistent eustachian valve, persistent thebesian valve, IVC connecting to LA, atresia of the right atrial ostium of the coronary sinus, supra-avalvular tricuspid stenosis, tricuspid

valve "stopper," IVC obstruction, and others. Knowledge of normal fetal development of the sinoatrial valves is helpful in understanding these cardiac derangements.

Persistence of the right sinus venosus valve has been seen in isolation and in association with hypoplastic right heart syndrome and ventriculocoronary artery communications (84), Ebstein malformation (85), and tricuspid atresia (86).

Embryology of the Valves of the Sinus Venosus

In the 3-week-old (4 mm) human embryo, the sinus venosus is external to the primitive RA. The right horn of the sinus venosus receives the hepatic vein (precursor to the IVC) and the anterior cardinal vein (precursor to the superior vena cava). The left horn of the sinus venosus is the embryologic precursor of the coronary sinus.

The right and left valves of the sinus venosus separate the sinus venosus from the primitive RA. The sinus venosus septum has already formed and joins the right and left valves of the sinus venosus (87).

In the 4-week-old (6 mm) human embryo, the septum primum appears and begins to septate the common atrium. At this stage, the opening of the sinus venosus into the common atrium is well guarded by the right and left valves of the sinus venosus (88).

In the 5- to 6-week-old (9 mm) human embryo, the sinus venosus has been absorbed into the common atrium. The right and left valves of the sinus venosus join cranially to form the septum spurium (23), which maintains the valves in a state of tension but plays no role in further embryogenesis. The septum secundum has begun to divide the common atrium from posterosuperior to anteroinferior. In subsequent embryologic development, the left valve of the sinus venosus retrogresses and is absorbed into the limbus region of the septum secundum. The right valve of the sinus venosus begins to enlarge.

By the time the human embryo reaches 3 months' gestation (36 mm), the right valve of the sinus venosus almost completely divides the RA into the sinus portion (sinus venosus) receiving the SVC, IVC, coronary sinus, and foramen ovale, and the muscular portion of the RA communicating with the tricuspid valve and the RAA (89).

At this point in embryologic development, the right valve of the sinus venosus almost completely segregates all systemic venous blood exiting the SVC, IVC, and coronary sinus from the tricuspid valve and tends to shunt it into the LA. One can predict the physiologic abnormalities of blood flow that might occur if there is partial or complete persistence of the right valve of the sinus venosus (Fig. 36.24).

In the great majority of humans, the right valve of the sinus venosus almost completely regresses by the time of birth. The remnant of the right valve of the sinus venosus where it separated the RA into two portions persists as the crista terminalis. In the normal human heart, the crista terminalis separates the anterior, muscular portion of the RA from the posterior, sinus venosus, or sinus portion of the RA. The superior portion of the right valve of the sinus venosus plus a portion of the sinus venosus septum persists as the eustachian valve guarding the inferior vena caval orifice. The inferior portion of the right valve of the sinus venosus plus a portion of the sinus venosus septum persists as the thebesian valve guarding the orifice of the coronary sinus (Fig. 36.24) (87).

Right Ventricular Outflow Tract Obstruction

This defect has been identified at echocardiography (90), on angiography (91), at operation, and at postmortem (92). By any of these methods, it appears as a windsock, parachute,

Figure 36.24. A: Diagram showing the normal appearance of the remnants of the right venous valve in the right atrium. The eustachian valve (Eust. V.) is seen at the entrance of the inferior vena cava (IVC) into the right atrium. The thebesian valve (Theb. V.) is seen at the right atrial orifice of the coronary sinus. B: Persistence of the embryonic right venous valve leads to diversion of the entire systemic venous return into the left atrium through the foramen ovale (FO). Multiple fenestrations of varying extent and size are often present (Chiari network) and allow some systemic venous blood to flow into the right ventricle through the tricuspid valve (TV). SVC, superior vena cava.

or spinnaker-like sack that originates in the RA and traverses the tricuspid valve, right ventricle, and pulmonary valve to obstruct either partially or nearly completely the blood flow to the pulmonary artery. On echocardiography, it can be imaged as a thin, mobile, linear structure originating in the RA and traversing the tricuspid valve to obstruct pulmonary flow.

Failure to recognize the nature of the windsock obstructing the pulmonary artery at operation can lead to death (92). On the other hand, successful resection of the pulmonary artery windsock results in return of normal physiology (90,91).

Tricuspid Valve Obstruction

This is a relatively more common anatomic abnormality. Lucas and Krabill (52) reviewed five autopsied cases from the material in the Jesse Edwards Registry of Cardiovascular Pathology and added five well-described cases from the literature.

Anatomy

Typically, in these cases, the orifice of the tricuspid valve is nearly occluded by a “windsock” or “stopper.” The windsock appears to be persistence of the right valve of the sinus venosus.

Associated Cardiac Anomalies

These 10 cases included four males and six females with an age range of newborn to 58 years. All cases had a patent foramen ovale or ASD. Two had significant associated congenital cardiac defects, one had D-transposition of the great vessels, and the other had L-loop (congenitally corrected) transposition of the great vessels, Ebstein anomaly of the left-sided tricuspid valve, and heart block. Two other cases had hemodynamically insignificant VSDs.

Clinical Features

Nine of these ten patients were cyanotic, and seven had significant right-sided heart failure. Echocardiographic imaging from a high right parasternal longitudinal view demonstrated an echo-reflective linear structure anchored to the RA near the IVC at one end and near the foramen ovale at the other side (93). A four-chamber view of the heart demonstrated a linear, mobile, echo-reflective structure moving toward the tricuspid valve in diastole and toward the posterior right atrial wall in systole.

Treatment

Operative resection of the windsock and closure of the ASD were attempted in four patients. All four survived and had no symptoms and normal physiology postoperatively (94).

Ahmad I. Alomari

INTRODUCTION

Vascular anomalies are relatively common heterogeneous disorders characterized by developmentally abnormal blood vessels including the venous, arterial, and lymphatic lineages. These anomalies may overlap clinically and radiologically creating considerable confusion in the clinical practice and published research. Nevertheless, the diagnosis and management of the vast majority of vascular anomalies fundamentally can be simplified if the proper nomenclature and classification are applied. Commonly used inaccurate terms such as lymphangioma, cystic hygroma, cavernous hemangioma, hemangioma, strawberry hemangioma, hemangiolymphangioma, and cavernoma should be abandoned for the more representative designation.

The binary classification proposed by Mulliken and Glowacki in 1982 (1) divides vascular anomalies into two major categories: (i) vascular tumors and (ii) vascular malformations. Vascular malformations can be either of the slow-flow (venous, capillary, and lymphatic) or fast-flow type (arteriovenous malformations (AVMs) and fistulas). The correct diagnosis and appropriate therapy require proper awareness of the clinical and imaging features of different types of vascular anomalies. Improper terminology can lead to the wrong diagnosis, mistreatment, and misdirected research efforts (2).

Unfortunately, terminological imprecision is still prevalent in the published literature. "Hemangioma," according to Hasanein et al. (1b) was used incorrectly in 228 of 320 of the publications (71.3%) analyzed. The authors also demonstrated that inaccurate designation of the vascular anomaly was associated with an increased risk of erroneous management.

EMBRYOLOGY AND GENETICS

The embryonic vascular network primarily is created via two major, distinct mechanisms: vasculogenesis and angiogenesis (3,4). The differentiation and growth of blood vessels from hemangioblasts of mesodermal origin forming the heart and the primitive vascular plexus is called "vasculogenesis," while the subsequent process of remodeling and expanding this network is referred to as "angiogenesis" (5). The distinction between arteries and veins is an early developmental process (6) with molecular differences between arterial and venous channels prior to the establishment of the circulation (7,8).

Due to the extensive, complex biologic pathways involved in the formation of normal blood vessels, developmental anomalies of the vasculature (both idiopathic and those caused by specific defects) are frequently seen.

Most vascular anomalies are sporadic with no identifiable familial or genetic predisposition. Nevertheless, specific mutations have been identified in many vascular anomalies and

syndromes. Inherited disorders of vessels include hemorrhagic telangiectasia (HHT, ENG, ALK1, or SMAD4 mutations), capillary malformation–arteriovenous malformation (CM-AVM, RASA1 mutation), cutaneomucosal venous malformation (VMCM, TIE2 mutations), glomuvenous malformation (GVM, GLOMULIN mutation), PTEN hamartoma tumor syndromes (PTEN mutation), Ataxia-telangiectasia (ATM mutation), cerebral cavernous malformation (CCM, CCM1-4 mutations), primary congenital lymphedema (Milroy disease, VEGFR3 mutation), among others (9a).

Several sporadic, complex syndromes are known to be associated with fast-flow vascular anomalies. Parkes Weber syndrome and CLOVES syndrome, two rare overgrowth syndromes, are associated with AV shunts and hypervascularity. AVMs and fistulas also have been reported in Noonan syndrome (bilateral multiple pulmonary arteriovenous fistulas [AVF] and duplicated renal collecting (9)), Ehlers-Danlos syndrome (10,11), VACTERL association and fibromuscular dysplasia (12), and liver hemangioma (13), among others.

Infantile hemangioma and rapidly involuting congenital hemangioma (RICH) are probably the most common vascular pediatric tumors and occasionally can be associated with arteriovenous shunts. For instance, hepatic RICH is typically a large solitary mass and might be associated with various types of transhepatic vascular shunts and high-output heart failure (14).

CLASSIFICATION

The well-known classification of vascular anomalies, proposed by Mulliken and Glowacki (1), divided them into two distinct types: tumors and malformations. This classification is based on clinical, histopathologic, and imaging differences (Tables 37.1 and 37.2).

Infantile hemangiomas (IHs), the prototype of vascular tumors, are common endothelial tumors that present in early infancy and spontaneously involute later in childhood. Congenital hemangiomas, a less common lesion, are present at birth. Endothelial cell tumors also include a spectrum of uncommon hemangioendotheliomas (such as kaposiform hemangioendotheliomas (KHEs) and epithelioid hemangioendotheliomas) and angiosarcoma.

Vascular malformations typically are present at birth and grow with the patient. Based on the cellular lineage and flow pattern, malformations are divided into slow-flow (including venous malformations [VMs], lymphatic malformations [LMs], capillary malformations [CMs] or combined malformations) and high-flow malformations (arteriovenous malformations [AVMs] and arteriovenous fistulae [AVF]).

Out of 375 pediatric vascular anomalies reviewed by Finn et al. (15), 96% of these lesions can be classified as tumors or malformations.

^aAssociated with Kasabach Merritt syndrome.

CLINICAL MANIFESTATIONS

Vascular Tumors

Infantile Hemangiomas

IHs are the most common tumors of infancy that present in the first few months of infancy or at birth in 4% to 5% of infants (16). IH is not fully developed at birth, though earlier signs (such as faint macular or telangiectatic stain) may herald the definitive manifestation of the lesion. Typically, IH undergoes rapid growth (proliferative phase) over a few months, then regresses spontaneously over years (involuting phase). IH, like many other vascular anomalies, has a predilection to affect the cervicofacial region. The lesions are known to disproportionately affect Caucasians, females, and premature infants.

Histologically, IH shows lobules and sheets of tightly packed, mostly capillary-sized vascular channels.

The tumor initially manifests as a well-margined reddish-purple lesion with variable size, shape, and depth of tissue involvement (Fig. 37.1). Superficial hemangiomas are limited to the skin and subcutis. Deep lesions affect the subcutis and adjacent anatomical spaces, typically sparing the skin and bone. Combined (deep and superficial) and multiple IHs are not uncommon. IHs also can be solitary (focal) or multiple (multifocal). Hemangiomas are usually rubbery, warm, and can be pulsatile.

TABLE 37.2 Vascular Malformations

Telangiectasia	Combined vascular malformations (CVM)
Capillary (Port wine stain)	Klippel-Trenaunay syndrome (CLVM)
Venous (VM)	Parks Weber syndrome (PWS)
Lymphatic (LM)	Servelle Martorell syndrome
Arterial-venous (fast flow) (AVM)	Proteus syndrome
Arterial	Capillary malformation-AVM
	Glomovenous malformation
	Clove syndrome
	Maffucci syndrome

Figure 37.1. Infantile hemangiomas of the face. The raised, well-margined reddish lesions have superficial (cutaneous) and deep portions.

In most patients with IHs, no treatment is necessary because most lesions regress over years without leaving significant scarring (17a). Nevertheless, complications of hemangiomas such as ulcers, bleeding, amblyopia (periorbital), airway obstruction (subglottic), and heart failure (liver) require prompt intervention (17a,17b).

The combination of posterior fossa malformations, cervicofacial, hemangiomas, arterial anomalies, cardiac defects, eye anomalies, and sternal clefting, or supraumbilical raphe, is referred to as "PHACES" Association (17).

PELVIS (or SACRAL) association is composed of a perineal hemangioma, external genitalia malformations, lipomyelomeningocele, vesicorenal abnormalities, imperforate anus, and skin tag (18,19).

Congenital Hemangiomas

Congenital hemangiomas are present and fully mature at birth. Rapidly involuting congenital hemangioma (RICH) and noninvoluting congenital hemangioma (NICH) demonstrate marked similarities in appearance, location, size, and equal sex ratio (20). RICH regresses in the first year of life while NICH persists. Glucose transporter protein (GLUT1), an immunohistochemical marker for IH, is not expressed in congenital hemangioma (21,22).

Liver hemangiomas represent a spectrum of lesions with variable clinical and imaging features. The large, solitary liver hypervascular tumors are RICHs, while the multifocal and diffuse types are histopathologically IHs (23) (Fig. 37.2). Hepatic hemangiomas typically are asymptomatic. However, they can cause high-output cardiac failure, liver dysfunction, hypothyroidism, coagulopathy, and abdominal compartment syndrome.

KHE is an infiltrative tumor with clinical and imaging features distinct from IHs. KHE typically is present at birth or appears shortly thereafter in early infancy, though they rarely can develop in adults. Histologically, KHE is characterized by a predominant Kaposi sarcoma-like, fascicular spindle cell growth pattern of epithelial cells, infiltrating nodules with slit-like, or crescentic vessels that are poorly canalized (26).

The tumor presents clinically with thickened, purple-ecchymotic skin discoloration (Fig. 37.3). KHE commonly is associated with Kasabach-Merritt phenomenon (KMP)

Figure 37.2. Liver hemangiomas. **A:** Hepatic RICH. Enhanced CT scan shows huge hypodense mass in the right lobe of the liver. Note peripheral enhancement and subcapsular locations. **B,C:** Multifocal hepatic infantile hemangioma. T2 and postcontrast T1 sequences demonstrate two focal, well-defined T2 hyperintense lesions that enhance following contrast administration. **D:** Diffuse hepatic infantile hemangioma. Enhanced CT scan reveals numerous, hypodense masses with peripheral enhancement almost completely replacing the liver parenchyma.

with platelet entrapment within the tumor leading to severe thrombocytopenia (24). KHE, unlike IH, is a solitary lesion, affects both genders equally, and has predilection for the trunk, extremities, retroperitoneum, and head and neck (26). It is locally invasive.

On imaging, the affected area exhibits thickening of skin with reticular infiltration of the skin, subcutis, and deeper tissue planes. The infiltrate is hyperintense on T2-WI and enhances on T1-WI following contrast administration (Fig. 37.4).

Imaging of Vascular Tumors

Ultrasonography is the initial, simple, and reliable imaging modality for many vascular tumors.

For infantile hemangioma, ultrasound images typically depict a solid, hypervascular mass with well-defined margins (Fig. 37.5). The feeding arteries and draining veins are enlarged. The former displays a low-resistance arterial spectral waveform.

Magnetic resonance imaging (MRI) is superior to CT scan in demonstrating the characteristic features of hemangiomas. On both modalities, IHs are well-defined, lobulated solid masses with homogeneous enhancement following contrast administration. The tumor demonstrates a homogeneously low or moderate intensity on T1-WI and high intensity on T2-WI magnetic resonance (MR) images. Flow voids within or around the lesion are caused by the dilated feeding arteries and draining veins (Fig. 37.6).

Angiography rarely is needed for diagnostic purposes. Angiography is an integral part of therapeutic embolization for the rare hemangiomas that are associated with heart failure. Typically, IHs demonstrate a hypervascular well-marginated mass with dense, prolonged capillary blush, enlarged feeding arteries, and draining veins (Fig. 37.7).

Congenital hemangioma usually displays a discoid cutaneous-subcutaneous well-defined mass with large feeding arteries and superficial vessels (Fig. 37.8). Angiographic findings of

Figure 37.3. Kaposiform hemangioendothelioma. Irregular patch of purple-ecchymotic skin thickening with overgrowth of the right thigh.

congenital hemangioma include inhomogeneous parenchymal staining, large, and irregular feeding arteries in disorganized patterns, arterial aneurysms, and direct arteriovenous shunts (25).

KHE characteristically demonstrates a network of subcutaneous reticular pattern in the subcutis and confluent intensities along the fascial planes. The infiltrate is hyperintense on T2-WI with thickening of the skin, underlying subcutaneous tissue, and involved deeper spaces. The lesion enhances homogeneously following contrast administration (Fig. 37.9).

Management of Vascular Tumors

Asymptomatic, nondisfiguring IHs can be monitored clinically without treatment. If treatment is indicated, successful medical management typically is achieved using systemic corticosteroids or propranolol. Alternatively, intralesional

corticosteroids can be used for IHs in critical locations where accelerated response is needed (e.g., periorbital, nasal tip).

Embolization of large arterial feeders and intratumoral shunts is reserved for hemangiomas causing high-flow heart failure. Typically, these lesions are hepatic and manifest early in infancy.

Single-agent chemotherapy currently is the mainstay treatment for KHE-associated KMP including the use of vincristine, cyclophosphamide, corticosteroids, interferon alfa-2a, and other agents (26).

Vascular Malformations

Slow-Flow Types

VENOUS MALFORMATIONS

VMs are the most common vascular malformations with a predilection for the cervicofacial region (27). VMs are typically solitary lesions, though a minority of patients have a genetic predisposition (such as in cutaneomucosal venous malformation and glomuvenous malformation). Blue rubber bleb nevus syndrome (Bean syndrome) is a rare sporadic disorder with soft tissue and gastrointestinal multiple VMs.

The classic histological features of VMs are irregular, venous-type channels lined by flat endothelium surrounded by scant (or absent) smooth muscles (28).

VMs are bluish, soft, and compressible masses. Lesions can be flat, slightly raised, or even exophytic. Calcified old clots (phleboliths) can be palpated and occasionally are tender (Fig. 37.10). As the solid component of VMs, composed of venous walls, membranes, and clots, is negligible, the size of the lesion predominantly is composed of stagnant blood. Hence, the volume of the VM increases with dependent positions and/or compression of the draining veins. Pain in VM is multifactorial. Clot formation is almost universal to VMs and some of the thrombosis episodes can incite swelling and pain. Pain also can be attributed to joint, muscle, and tendon involvement and weakening. Recurrent hemarthrosis, particularly of the knee joint, is predisposed by synovial involvement and usually results in chronic pain and joint degenerative changes.

Figure 37.4. Ultrasonography of infantile hemangiomas. A: Diffuse enlargement of the right parotid gland caused by an infantile hemangioma. B: Marked hypervascularity of the lesion with enlarged feeding arteries.

Figure 37.5. MRI of infantile hemangiomas. Two well-defined, lobulated soft tissue masses in the left occipital and parapharyngeal spaces. Note the hyperintense signal and flow voids (enlarged vessels) on axial T2 sequence (A) and strong enhancement following contrast administration on axial T1 sequence (B).

Symptoms may worsen with menses, pregnancy, and use of oral contraceptive pills. Specific locations of VMs can result in additional morbidity: joints (e.g., hemarthrosis), extensive osseous involvement (bone deformity and fracture), airways (obstruction), and intestines (chronic bleeding).

Localized intravascular coagulation (LIC) commonly occurs with large VMs. This typically asymptomatic phenomenon is

characterized by elevated D-dimer and hypofibrinogenemia with normal or slightly decreased platelet counts (29). These changes are due to constant intralesional thrombosis. Therefore, basic coagulation parameters (CBC, PT/INR, PTT, fibrinogen, and D-dimers) are obtained prior to major interventions.

IMAGING OF VASCULAR TUMORS

Most VMs can be diagnosed clinically and small, superficial lesions may require no further evaluation. Nevertheless, larger lesions can be characterized by ultrasonography and MRI in terms of the actual size, extension, and confirmation of the diagnosis, particularly for deeper lesions.

Sonographic findings of VMs are compressible, blood-filled masses surrounded and internally septated by thin venous walls (Fig. 37.11). Clots or phleboliths are typically incompressible, hyperechoic oval or round filling defects. Color and spectral Doppler interrogation typically shows no flow within the venous spaces. Ultrasonography is invaluable to guidance guiding image-guided treatment.

Recommended MRI sequences for VMs (and essentially all other vascular anomalies) include pre- and postcontrast T1-WI and T2-WI, all with fat saturation. MR venography may demonstrate the local venous system and provide spatial information, especially for phlebectasia of the extremities (Fig. 37.12), but is not routinely needed.

Typical MRI appearances of VMs are hyperintense masses on T2-WI containing thin curvilinear network of septations with focal hypointense lesions corresponding to phleboliths (Fig. 37.13). VMs enhance heterogeneously on T1-WI following contrast administration. Intralesional or ascending venography is not typically needed as a diagnostic study. Venography shows amorphous, spongiform spaces with stagnant flow and variable types of draining veins (Fig. 37.14). CT scan is particularly useful in assessing osseous VMs.

Figure 37.6. Rapidly involuting congenital hemangioma (RICH). Large, solid hypervascular lesion of the right thigh with red-purple overlying skin. The lesion was present at birth and regressed rapidly within months.

Figure 37.7. Kaposiform hemangioendothelioma of the thigh. Axial T2 sequence (A) shows skin thickening, reticular subcutaneous infiltrate, and epifascial confluence of signal. Following contrast administration, the lesion enhances strongly (B).

Other less frequent types of VMs include phlebectasia (congenital varicosity), persistent embryonic veins, and venous aneurysms. These less common venous anomalies can be isolated or syndromic (e.g., Klippel-Trenaunay and CLOVES syndromes).

TREATMENT OF VENOUS MALFORMATIONS

VMs can be minor, asymptomatic, and require no immediate treatment. Nevertheless, the natural history of VMs is progressive growth and potential symptoms. VMs causing disfigurement or located within sensitive areas (e.g., joints, airways) may necessitate preemptive therapy earlier in childhood.

Compression stocking for VMs of the extremities, particularly the superficial ones, may reduce the blood contents of the VMs and control symptoms. Minimally invasive treatment approaches to VMs include sclerotherapy, laser, and photodynamic therapy.

Sclerotherapy is widely accepted as the initial treatment of choice at many specialized centers. Proper preoperative imaging (typically an MRI) is paramount to planning and performing the procedure. Sclerotherapy, particularly for extensive lesions, is performed under general anesthesia. We do not routinely treat mild forms of coagulopathy prophylactically. Ultrasound guidance using a high-resolution probe

Figure 37.8. Venous malformation. A: Left cheek exophytic VMs with limited cutaneous involvement. B: Tongue VMs with slightly raised contour.

Figure 37.9. Ultrasonography of venous malformation. VMs of the chest wall with fluid-filled compressible spaces and compartmentalization by thin septa. Note the fluid-fluid levels.

is essential for locating the lesions and directing the needles. The tools required for sclerotherapy generally are inexpensive and simple.

Access needles of variable gauges and lengths (e.g., 20- to 21-gauge angiocatheters or micropuncture needles) are placed within the VMs under sonographic guidance. Intralesional placement is confirmed by free blood return and intralesional venography. The latter is performed to delineate the size of the opacified portion and the draining veins as well as to exclude extravasation outside the VMs (Fig. 37.15).

It is crucial to implement x-ray dose reduction techniques such as proper collimation, filtration, and last image hold. Complex anatomical location, such as the head and neck, may require biplane imaging for adequate visualization of the VMs. Ascending venography of the entire limb is helpful in delineating the deep venous system that should be protected and observed throughout the procedure. Contrast material should be diluted with saline without jeopardizing the imaging quality. After confirming the proper position of the needle, the lesion is injected with the sclerosant under fluoroscopic and/or sonographic guidance (Fig. 37.16). Dual-needle technique is useful in focal lesions where two needles (or more) are simultaneously placed within the lesions. The sclerosant is injected through one needle displacing blood via the other (draining) needle. No attempt is made to aspirate the sclerosant. Whenever possible, blood is aspirated or compressed out of the VM immediately prior to the injection of the sclerosant. The volume of the sclerosant typically is equal to (or more than) the

Figure 37.10. MRI of venous malformation. **A:** Axial T2 sequence showing the hyperintense signal of the VMs of the chest wall with herniation into the thoracic cavity. The signal reflects the dominant fluid (blood) component. Note multiple hypointense foci representing phleboliths. **B:** Partial, heterogeneous enhancement on axial T1 sequence following contrast administration.

Figure 37.11. Intralesional venography of the VMs. The amorphous, spongiform communicating venous spaces are opacified with direct injection of contrast. The small draining veins communicate with the intercostal veins.

volume of contrast required to opacify the lesion. The rest of the lesion is then treated similarly.

Extralesional extravasation of sclerosant likely is the cause of most of complications. Problematic or positional accesses should be abandoned for safer ones. On venography, extravasation is manifested as geometric, smooth, or lenticular contrast collection around the tip of the needle, expansion artifacts, and persistent tissue infiltration. Cessation of blood return from the access needle and resistance for further

Figure 37.12. Sclerotherapy of VMs with sodium tetradecyl sulfate foam. Ultrasonography reliably differentiates between the portion of the VMs injected with the foam (hyperechoic signal with air artefact) and the untreated portions.

Figure 37.13. Embolization of congenital phlebectasia of the right lower extremity. **A:** MRV of the leg demonstrating the extensive superficial phlebectasia superimposed over the patent deep venous system. **B:** Multiple glue casts permanently occluded the anomalous, ectatic superficial veins and diverted the flow into the deep venous system.

injection should not be overlooked as they may represent extravasation.

The overlying skin may demonstrate immediate changes during injection of the sclerosant into superficial lesions.

Control of the drainage veins, when needed for large VMs, can be achieved with direct pressure (manual or with an ultrasound probe or clamp), positioning, or by using a tourniquet. The latter should be inflated for a short period (typically a few minutes) so it does not cause unnecessary stagnation and accumulation of sclerotherapy by-products in the normal deep veins. Ultrasound and fluoroscopy can be used complementarily to confirm that the treatment covered the intended parts of the lesions.

Due to hemolysis of blood within the VM, hemoglobinuria and oliguria may develop. Perioperative hydration is necessary. A urinary catheter is inserted to observe for these complications. Following the treatment, the treated site is elevated and pain is prophylactically controlled. We do not routinely administer antibiotics or steroids. Prolonged intubation in the ICU is mandatory for critical airway VMs. Alternatively, tracheostomy may be placed.

Blistering and ulceration of the overlying skin are managed with standard wound care. Hemoglobinuria and oliguria are common and are managed successfully with hydration and diuresis. Compartment syndrome and neuropathy are often avertable by avoiding extravasation and excessive therapy.

The commonly used sclerosants for VMs are dehydrated ethanol, sodium tetradecyl sulfate (STS), polidocanol, sodium morrhuate, ethanolamine oleate bleomycin, and alcohol solution of zein. Ethanol can be injected pure or opacified with ethiodized oil contrast (e.g., Ethiodol). The mixture is injected under digital subtraction fluoroscopy and caution is exercised to avoid extravasation (Fig. 37.17). Injection of ethanol can be very painful and irritating causing transient tachycardia

Figure 37.14. Macrocystic lymphatic malformation of the base of the neck. **A:** The photograph shows a left cervical mass with normal skin. **B:** Sonographic image reveals the cystic nature of the mass with thin walls and septa. Fat saturated axial T2 (**C**) and postcontrast T1 (**D**) MRI sequences show a simple cystic lesion with no solid component. The thin walls and septations enhance after contrast injection.

and tachypnea. Large volumes of ethanol and hemolysis by-products entering into the systemic veins can cause life-threatening pulmonary hypertension and cardiopulmonary arrest. The maximum amount of ethanol typically is limited to 0.5 to 1.0 mL/kg per session (30). Elevated serum ethanol can cause respiratory depression, arrhythmias, seizures, rhabdomyolysis, and hypoglycemia (31).

STS 3% () is a widely used sclerosant which can be used in foam or liquid forms. The foam form is likely to be more effective and can be reconstituted by mixing STS with an equal volume (or more) of air (or CO₂) through a three-way stopcock. Ethiodol can be added to the mixture (1:10) to stabilize the foam. Visualization of the foam is superior with sonography.

Embolic agents such as *N*-butyl cyanoacrylate glue, ethylene vinyl alcohol (Onyx), and coils can be used as adjuvant tools, particularly for filling huge anomalous venous spaces, to control draining veins, or preoperatively. These agents are not bioabsorbable and typically are not used as primary treatment

for VMs. Endovenous laser photocoagulation, in combination with sclerotherapy and venous embolization, can be useful in selective cases of phlebectasia of the extremities (Fig. 37.18).

The two major factors to gauge the response to sclerotherapy are pain relief and size reduction. While pain control is achieved in the vast majority of patients, shrinkage of the VM usually requires multiple procedures. For large and disfiguring VMs, sclerotherapy can be combined with surgical resection. When multiple treatments are required, procedures are scheduled 6 to 8 weeks apart.

For diffuse involvement of the limb or organ, “targeted” sclerotherapy of the painful portions may offer symptomatic relief.

LYMPHATIC MALFORMATIONS

LMs are divided into several main subtypes, namely, the macrocystic, microcystic, combined form, and anomalies of the central conducting lymphatics. Lymphedema also falls within the spectrum of LM. Erroneous names are still widely used (such as cystic hygroma, lymphangioma, and hemangiolymphangioma)

Figure 37.15. Microcystic lymphatic malformation of cervicofacial region with macroglossia.

and should be abandoned. Macrocystic LMs are composed of lymph-filled cysts and microcystic LMs consist of microscopic lymphatic spaces not identifiable with imaging tools. Microcystic LMs tend to be extensive and infiltrative through the tissue planes with associated bony overgrowth, particularly in maxillofacial area. The overlying skin is usually intact though capillary stains or lymphatic vesicles are occasionally encountered.

Histopathologically, LMs have a thick myxoid fibrous wall containing myofibroblasts and smooth muscle cells with abnormal channels which can be empty, contain lymph, proteins, or blood (28).

Symptoms related to LMs can vary from mild disease to significant pain, recurrent infection, lymphatic or chylous leak, mass effect, and deformities. LMs rarely involute spontaneously. Hence, early and appropriate treatment of LM to provide symptomatic, functional, and cosmetic improvement is recommended. Spontaneous painful swelling (flare-ups) is commonly predisposed by systemic or local infections such as viral illnesses. Intralesional bleeding also is common, particularly with flare-ups. LMs most commonly affect the cervicofacial, axillary, and pelvic regions.

Sclerotherapy is the first-line management for LMs. Most procedures are performed with general anesthesia. In general, fluid-filled spaces are cannulated with 21- or 20-gauge needles using ultrasound guidance, fluid is aspirated, and the sclerosant is injected into the macrocysts under sonographic or fluoroscopic guidance. Sclerosants generally are not removed

after injection (32–34). Large cysts can be drained with a pig-tail catheter and sclerosed repeatedly.

Ultrasound-guided procedures may not need any contrast opacification.

Commonly used sclerosing agents for LMs include ethanol, doxycycline, STS, bleomycin, and OK-432 (35). Doxycycline is a broad-spectrum antibiotic from the tetracycline class. It is used for pleurodesis in pediatric patients. A report of its use in a small group of patients with unresectable LMs concluded that doxycycline is a safe and, to a varying degree, effective sclerosing agent (24). We usually add 10 mL of half strength contrast medium to 100 mg of lyophilized doxycycline powder (Doxo 100 and 200, American Pharmaceutical Partners, Inc., Los Angeles, CA). The resulting opacified solution of 10 mg/mL is then injected directly into the malformation under fluoroscopic and/or sonographic guidance. OK-432 is packaged as a powder in 0.1- or 0.5-mg vials. The OK-432 solution is prepared by dissolving 0.1 mg of OK-432 in 10 mL of normal saline.

CAPILLARY MALFORMATIONS

CMs are pink-red skin macules with a tendency to affect the cervicofacial region. Extensive CMs can be occasionally associated with hypertrophy of the affected region. CMs also occur in several syndromes with complex vascular anomalies such as Sturge-Weber syndrome, Klippel-Trenaunay syndrome, Parkes Weber syndrome, CLOVES syndrome, and CM-AVM (RASA-1 mutation).

IMAGING OF VASCULAR ANOMALIES

Focal VMs are hyperintense on T2-weighted MRI sequences with thin linear septations. VMs enhance heterogeneously and partially following contrast administration and fluid–fluid levels are common. MR venography may demonstrate the local venous system but is not routinely needed to establish the diagnosis. Conventional venography rarely is utilized for diagnosis but is an integral part of percutaneous treatment. CT scan can provide some additional information for bone or deep mesenteric VMs, but generally is less helpful with the soft tissue lesions. Focal intralesional hypointense foci are caused by phleboliths. Phleboliths also can be detected on CT scan and plain radiographs. Ultrasonography demonstrates the compressible blood-filled spaces with internal septations and phleboliths. Venous flow typically is not visualized due to extremely sluggish flow of blood within VMs.

On MRI, lymphatic macrocysts are similar to any other simple cysts with thin walls. Internal septations or a conglomeration of multiple cysts is common. Macrocysts typically demonstrate enhancement of wall and/or internal septa following the administration of contrast but not of the fluid contents. The microcystic LM appears as an ill-defined soft tissue thickening on sonography. Evidence of intralesional bleeding is common and causes the typical fluid–fluid level. Microcystic LMs typically are solid T2 hyperintense lesions with a poorly defined, infiltrating nature with some heterogeneous postcontrast enhancement and overgrowth of the affected tissue. For CMs, imaging is not usually required to establish the diagnosis except if there is an associated malformation, overgrowth, or syndrome.

FAST-FLOW VASCULAR MALFORMATIONS

An AVM is composed of a primitive network of connecting channels (nidus) bypassing the capillary bed. There is no associated mass. AVMs are rare lesions and are congenital though typically stay dormant during childhood.

AVMs result in major local and sometime systemic hemodynamic disturbances. The arterial flow preferentially is diverted through the AV shunt and into the draining veins that may result in tissue ischemia and venous hypertension. These hemodynamic changes manifest clinically as tissue overgrowth,

Figure 37.16. Ultrasonography of arteriovenous malformation of the left upper extremity. Images (A and B) showing increased blood vessels around the eroded bony cortex with turbulent flow and intraosseous dilated draining sac. C: Doppler spectral wave with low-resistance pattern (increased diastolic flow).

hyperemia, pain, pulsatility, tissue loss, bleeding, and, infrequently, high-output heart failure.

Direct simpler shunts between an artery and a vein are called AVFs, such as seen in pulmonary AVFs in HHT and vein of Galen malformation. AVFs commonly are acquired related to traumatic and iatrogenic causes. Congenital AVF may present early in infancy with high-output heart failure.

Schobinger staged AVMs and described the natural progression of these lesions from quiescence (stage 1) to expansion (stage 2) to destruction: pain, bleeding, ulceration (stage 3), and in major AV shunts to stage 4 (decompensated heart failure) (36).

CT and MRI studies demonstrate dilated feeding arteries and draining veins without a discrete mass. On MRI, signal

abnormalities may be present in the surrounding tissue representing fibrofatty changes, edema, and disorganized overgrowth. Osseous involvement manifest as overgrowth and lytic changes with diffuse abnormal marrow signal.

Angiography demonstrates dilation of the feeding arteries with tortuosity, AV shunting, and even greater dilation of draining veins. In a diffuse or early-stage AVM, a blush with early venous opacification may be seen rather than a discrete nidus.

Arterial and venous embolization are preferred to surgical resection and often are performed in a staged fashion. Arteries supplying the nidus are selectively embolized at the nidus level, not proximally, via microcatheter access and high-quality selective angiography. Permanent liquid or semiliquid agents

Figure 37.17. MRI of arteriovenous malformation. Axial T2 (A) and postcontrast T1 (B) MRI sequences show a tangle of flow voids (enlarged blood vessels) around the proximal aspect of the radius bone. Note lack of soft tissue mass.

Figure 37.18. Angiography and embolization of AVM. A: Early arterial phase shows dilated arterial feeders arising from the lower segment of the left brachial artery. B: Early filling of large draining veins with aneurysmal changes of the immediate draining segments. C: The veins of the upper limb are dilated and hyperdynamic. D: Angiography following direct percutaneous access to the intraosseous draining sac within the distal humerus. The communications with the normal veins are clearly illustrated. E: Following embolization of the draining veins within and around the distal humerus, completion angiography showed effective cessation of shunting.

(ethanol, glue and Onyx) are injected under fluoroscopy into the nidus and immediate draining vein.

Temporary embolic agents, such as particles, can be used preoperatively to devascularize a selective focal lesion with tiny channels.

For AVMs with dominant draining veins, transvenous embolization, typically done with coils and other permeant agents, may provide superior results to transarterial embolization, particularly with numerous feeding arteries.

Tricuspid Atresia, Stenosis, Regurgitation and Uhl's Anomaly

Michael L. Epstein

Diseases of the tricuspid valve are relatively rare. This chapter deals with the more common forms of congenital malformations. Acquired disease of the tricuspid valve is extremely uncommon, other than infections (endocarditis) associated with illicit drug use or long-term use of indwelling intravenous catheters. These issues are not discussed in this chapter, but can be found elsewhere in this textbook.

TRICUSPID ATRESIA

The congenital heart defect known as tricuspid atresia can be defined as a complete absence of the tricuspid valve with no direct communication between the right atrium and right ventricle. This defect invariably leads to some degree of hypoplasia of the right ventricle. As a result of the absence of flow from the right atrium into the right ventricle, there is an obligatory right-to-left shunt at the atrial level, through either an atrial septal defect or a widely patent foramen ovale. There also must be a communication between the systemic circulation and the pulmonary circulation, usually in the form of a ventricular septal defect (VSD). Occasionally, however, there is associated pulmonary atresia, and pulmonary blood flow is supplied by a patent ductus arteriosus. This cardiac malformation, first described by Kreysig in 1817 (1), is uncommon and was found in fewer than 3% (0.056 per 1,000 live births) of patients reported in the New England Regional Infant Cardiac Program between 1968 and 1974 (2). Although tricuspid atresia usually occurs as an isolated defect, multiple cardiac anomalies have been reported in $\leq 20\%$ of patients. The cause of this defect is unknown. To date, no specific genetic marker responsible for this defect has been found (3).

Pathology

Because development of the tricuspid valve is related to the inflow (sinus) portion of the right ventricle, in patients with tricuspid atresia, the inlet portion of the right ventricle is absent. The right ventricle is composed largely of the infundibular portion and an incompletely formed trabecular portion. If a large VSD is present, the trabecular portion of the right ventricle may be better developed, resulting in a larger right ventricular cavity. On the other hand, if no VSD is present, the right ventricle is rudimentary or may be absent entirely. In this circumstance, the pulmonary valve also will be atretic.

The atretic tricuspid valve is represented by a dimple in the floor of the right atrium (Fig. 38.1). The resulting membrane is usually muscular but may be fibrous. The interatrial communication is usually a widely patent foramen ovale but may be a secundum atrial septal defect or, rarely, an ostium primum defect associated with an atrioventricular septal defect. When a VSD is present, it is usually perimembranous but also

may occur in the muscular septum or as a component of an atrioventricular septal defect, although the latter is rare. In the presence of a large VSD, the pulmonary flow is unobstructed. On the other hand, pulmonary blood flow can be restricted by the presence of a small VSD, pulmonary valve stenosis or pulmonary annular hypoplasia, or severe hypoplasia of the right ventricular outflow tract.

Tricuspid atresia may occur with normally related great arteries or in association with d-transposition of the great arteries (Fig. 38.2). In patients with associated transposition, the right ventricle forms a subaortic chamber, and there may be restriction to blood flow into the systemic circulation if the VSD is small. The clinical presentation of infants with tricuspid atresia often depends on associated anomalies, such as the presence of transposition of the great arteries, VSD coarctation, or pulmonary stenosis.

The various forms of tricuspid atresia usually are classified in a manner initially proposed by Kuhne (4) and later modified (5). Type I describes patients with normally related great arteries and occurs in 70% to 80% of patients with tricuspid atresia. Type II refers to patients with D-transposition of the great arteries and occurs in 12% to 25% of patients. Type III, a relatively uncommon form of tricuspid atresia occurring in only 3% to 6% of patients, is used by some authors for those patients born with more complex associated lesions such as congenitally corrected transposition or malposition of the great arteries. Perhaps type III might best be used to identify patients with all forms of more complex associated lesions, such as truncus arteriosus or atrioventricular septal defect.

Types I and II have been subclassified (Table 38.1). The subclassification for type I patients relates to the presence or size of a VSD. Type Ia refers to patients with no VSD and associated pulmonary atresia. Type Ib patients have a small VSD and some degree of restriction to pulmonary blood flow. Type Ic patients have large VSDs and no pulmonary stenosis. Obviously, there may be some overlap in classification in a particular patient. It is common for the VSD to decrease in size, thereby changing a patient's classification (6). In type II patients, the subclassifications relate to the degree of restriction of pulmonary blood flow directly from the left ventricle. Type IIa refers to patients with pulmonary atresia, type IIb refers to patients with pulmonary stenosis, and type IIc refers to patients with no obstruction into the transposed pulmonary artery. The physiology in type II patients may vary considerably, depending on the size of the VSD, but the subclassification does not consider this variation. Type III patients are uncommon, and subclassifications generally are not used.

Additional cardiovascular abnormalities are present in $\leq 20\%$ of all patients but are less common in those with normally related great arteries. Coarctation of the aorta is the most significant associated cardiac abnormality and occurs in approximately 8% of patients with tricuspid atresia. Other cardiac lesions include persistent left superior vena cava (SVC), juxtaposition of the atrial appendages, and right aortic arch.

Figure 38.1. Pathology specimen seen through an opened right atrium. The *arrowhead* indicates the muscular membrane in place of the tricuspid valve. The *arrow* indicates the patent foramen ovale.

Physiology

Normally Related Great Arteries

Because the only egress of blood from the right atrium occurs through the atrial septum, systemic venous return mixes completely with pulmonary venous return in the left atrium and subsequently flows across the mitral valve into the left ventricle. In patients with a VSD and a patent right ventricular outflow tract, blood is ejected directly into the normally arising aorta as well as through the VSD and the hypoplastic right ventricle into the pulmonary artery. The amount of pulmonary blood flow depends on the size of the VSD and the presence or absence of obstruction into the pulmonary artery. As the pulmonary vascular resistance decreases in the newborn infant, pulmonary overcirculation may develop.

Cyanosis is invariably present to some extent because of complete mixing of the pulmonary and systemic venous returns. The degree of cyanosis depends on the magnitude of pulmonary blood flow. Pulmonary overcirculation will not

Figure 38.2. Diagram depicting anatomy of tricuspid atresia type I (normally related great arteries) and type II (D-transposition of the great arteries). In these figures, both the atrial and ventricular septal defects are shown to be large. Ao, aorta; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

TABLE 38.1 Classification of Tricuspid Atresia

Type I	Normally related great arteries
	a. Intact ventricular septum with pulmonary atresia
	b. Small VSD and pulmonary stenosis
	c. Large VSD without pulmonary stenosis
Type II	Transposition of the great arteries
	a. VSD with pulmonary atresia
	b. VSD with pulmonary stenosis
	c. VSD without pulmonary stenosis
Type III	Transposition or malposition of the great arteries. Associated complex lesions, that is, truncus arteriosus, atrioventricular septal defect

occur when the pulmonary vascular resistance decreases in patients with a restrictive VSD or some form of pulmonary stenosis, but the degree of cyanosis is likely to be greater. In patients with an intact ventricular septum or pulmonary valve atresia, pulmonary blood flow is supplied through a patent ductus arteriosus. The size of the ductus arteriosus will determine the degree of pulmonary blood flow and consequently the degree of cyanosis.

Transposed Great Arteries

Pulmonary overcirculation occurs within the first few weeks of life in most patients with tricuspid atresia and D-transposition of the great arteries because obstruction to flow into the transposed pulmonary artery, which arises directly from the left ventricle, is uncommon. In these type II patients, the presence of a restrictive VSD or infundibular narrowing results in obstruction to systemic blood flow. If the obstruction is severe with resultant diminished systemic circulation, the infant may present with hypotension or shock and metabolic acidosis.

Other abnormalities of physiology may be present, depending on associated defects. For example, in a patient with a restrictive interatrial communication, marked hepatomegaly would be present with signs of diminished cardiac output as well as diminished pulmonary blood flow. In the presence of an associated coarctation of the aorta, the physiology of the type of tricuspid atresia would be present along with associated

findings of the coarctation, most notably diminished lower-extremity pulses and perfusion.

Clinical Features

Systemic arterial desaturation is present to some extent in every patient with tricuspid atresia because of complete admixture of the systemic and pulmonary venous returns (6). Although cyanosis may not be perceived immediately, most patients with tricuspid atresia are noted to be cyanotic by 1 week of age. Heart murmurs are almost always present. If there is no significant obstruction to pulmonary blood flow, cyanosis may not be apparent for some time. Symptoms of pulmonary overcirculation and resultant heart failure are likely to develop in these patients as the pulmonary vascular resistance diminishes. Cyanosis will be more apparent in patients with diminished pulmonary blood flow, but they will not develop pulmonary overcirculation. Hypercyanotic spells can occur in patients with tricuspid atresia as a result of either a decrease in the size of the VSD or infundibular narrowing (7). The physiology of these spells is similar to that seen in patients with tetralogy of Fallot and indicates the need for urgent surgery.

Patients with D-transposition of the great arteries usually present with pulmonary overcirculation; pulmonary stenosis is rare. When these patients have large VSDs, it is difficult to distinguish clinically between these patients (type IIc) and those with normally related great arteries and unobstructed pulmonary blood flow (type Ic).

On physical examination, newborn infants with tricuspid atresia are usually of normal size and demonstrate varying degrees of cyanosis. A left ventricular impulse is likely to be more prominent than a right ventricular impulse. A thrill may be palpable if the VSD is restrictive. The first heart sound is single and often accentuated. The second heart sound is often single, but two components may be heard, especially in infants with normally related great arteries and minimal pathology of the pulmonary valve. A holosystolic murmur may be heard as a result of flow through the VSD, or an ejection murmur may be more prominent because of obstruction through the right ventricular outflow tract. If pulmonary blood flow is increased significantly, a third heart sound and middiastolic rumble may be heard at the apex. The liver may be enlarged, especially in infants with a restrictive interatrial communication. Pulses are readily palpable in all extremities unless an associated coarctation of the aorta is present.

In older patients who either have not undergone any surgery or have had only a palliative aortopulmonary shunt, cyanosis will be more apparent and clubbing of the digits will develop. Additional physical findings will be present depending on the type of surgical intervention. For example, pulses in an arm will be diminished or absent if a previous classic Blalock-Thomas-Taussig shunt has been performed on that side.

Electrocardiographic Features

The electrocardiogram (ECG) from patients with tricuspid atresia is often helpful in the differential diagnosis of a cyanotic newborn (7–9). Right atrial enlargement may or may not be present at birth but often develops in older infants and children. Interestingly, there is no relationship between the amplitude of the P wave and the presence or absence of restriction at the interatrial communication. In patients with increased pulmonary blood flow, combined atrial enlargement may be present. The PR interval is normal in most patients with tricuspid atresia.

In most infants with cyanotic heart disease, the mean QRS frontal plane axis is rightward and inferior with prominent right ventricular forces. The ECG from a patient with tricuspid atresia, on the other hand, usually demonstrates a frontal plane QRS axis that is leftward and superior, and the anterior rightward forces are diminished (Fig. 38.3). This is especially true for type I patients, in whom about 85% of the ECGs demonstrate left-axis deviation. In patients with associated D-transposition of the great arteries (type II), the frontal plane QRS axis is evenly divided between a leftward superior axis and an axis that is directed inferiorly and to the left. In either event, right ventricular forces are usually diminished. Patients with tricuspid atresia and increased pulmonary blood flow often have ECGs demonstrating tall R waves and deep Q waves in lead V6. The ECG in patients with diminished pulmonary blood flow often shows small R waves with shallow Q waves (9).

In some patients, especially older patients, biphasic or inverted T waves may be present in the left precordial leads (V5, V6), with or without associated ST-segment depression (Fig. 38.4). The significance of this finding is unclear because these patients often have no myocardial dysfunction.

The cardiac rhythm is generally sinus. Atrial tachyarrhythmias, such as atrial flutter or fibrillation, may occur in older patients, especially those with restrictive atrial communications

Figure 38.3. Standard 12-lead ECG and lead II rhythm strip from an infant with tricuspid atresia and normally related great arteries. Note right atrial enlargement, leftward superior QRS axis, and diminished right ventricular forces. The precordial leads are recorded at half standard.

Figure 38.4. Standard 12-lead ECG and lead II rhythm strip from an older child with tricuspid atresia and normally related great arteries. Note leftward superior QRS axis, diminished right ventricular forces, left ventricular hypertrophy or enlargement, and T-wave changes. Precordial leads are recorded at half standard.

and dilated hypertensive right atria. Following completion of surgery to separate the systemic and pulmonary circulations (modified Fontan procedure), arrhythmias are relatively common and occur in $\leq 48\%$ of patients (10). Atrial tachyarrhythmias are encountered most commonly, but bradyarrhythmias and ventricular arrhythmias may occur.

Radiographic Features

The heart size is usually normal in infants with tricuspid atresia. In patients with no obstruction to pulmonary blood flow (types Ic and IIc), cardiomegaly is likely to develop from the increased volume load on the left cardiac chambers as pulmonary resistance decreases. In this circumstance, the pulmonary vascular markings will be prominent. Patients with obstruction to pulmonary blood flow will have normal or diminished pulmonary vascular markings, and heart size will remain normal. The cardiac silhouette is often globular shaped with a concavity in the region of the main pulmonary artery (MPA). The right-sided heart border may appear prominent as a result of dilation of the right atrium, especially in older infants and children.

Echocardiographic Features

Echocardiography has become the diagnostic procedure of choice. This noninvasive diagnostic modality has markedly diminished the need for cardiac catheterization for this lesion. The anatomy of tricuspid atresia is easily defined with two-dimensional echocardiography (11). Indeed, this technique has proven so accurate that most details of the anatomy are easily determined on fetal echocardiographic studies (12,13). M-mode echocardiography is of limited usefulness. Its value is mainly for quantitating the size and function of the left ventricle. The left ventricular cavity may be dilated, especially in patients with increased pulmonary blood flow. Ventricular function is usually normal but may become depressed because of chronic volume overload and hypoxemia, especially in older patients who have not undergone surgery or who have undergone only a palliative shunt.

In the vast majority of patients, all cardiac anatomic details are easily defined. Because the tricuspid valve is easily visualized by echocardiography, the presence of an imperforate linear echo density in the location of the normal tricuspid valve

confirms the diagnosis (Fig. 38.5). Unless pulmonary atresia is a concomitant defect, echocardiography also can demonstrate the presence of two semilunar valves and great arteries. Initial management may be different, depending on the great artery relationship; therefore, it is especially important to confirm the relationship of the great arteries by imaging techniques such as identifying the bifurcation of the pulmonary artery or origin of the coronary arteries. Determining the presence and size of a VSD is almost always possible. It is also important to visualize the atrial septum to evaluate the size of the interatrial communication. If there is restriction to flow between the atria, cardiac catheterization and balloon septostomy may be necessary. Finally, echocardiography usually shows major associated lesions, such as coarctation of the aorta.

The color Doppler portion of the echocardiogram will confirm the absence of a direct communication from the right atrium into the right ventricle and will demonstrate the right-to-left shunt at the atrial level. This portion of the echocardiographic study will define the physiology of pulmonary blood flow, such as restriction through the VSD, narrowing of the right ventricular outflow tract, or obstruction to pulmonary blood flow at the pulmonary valve annulus. It also is important to identify the presence and severity of mitral valve regurgitation, which is an important consideration for subsequent intervention.

Serial echocardiograms are important to evaluate the hemodynamic status of a patient following an initial surgical palliation (aortopulmonary shunt or pulmonary artery banding). Using the Doppler technique, pulmonary artery pressure can be estimated by determining the pressure gradient through the shunt or across the band. Following a more definitive surgical palliation, such as a modified Fontan procedure, echocardiography is the most effective means of monitoring these patients for the development of complications, such as ventricular dysfunction, mitral valve insufficiency, or obstruction to flow from the right atrium into the pulmonary arteries. These patients have a sluggish flow pattern through the right side of the heart and are at risk of developing thrombi in the right atrium. Echocardiography is an excellent means by which thrombi can be detected. For patients with recurrent atrial tachyarrhythmias, especially atrial flutter or fibrillation, transesophageal echocardiography may be necessary to rule out the possibility of a thrombus being present.

Figure 38.5. Echocardiographic views of an infant with tricuspid atresia and normally related great arteries. **A:** Apical four-chamber view demonstrating a thick linear echo-dense membrane in place of the tricuspid valve. There is a large communication between the right atrium and the left atrium. The arrow indicates a ventricular septal defect that measures 7 mm in this view. Note the hypoplastic right ventricle. **B:** A modified subcostal short-axis view demonstrating the membrane replacing the tricuspid valve. The hypoplastic right ventricle and ventricular septal defect are visualized. The right ventricular outflow tract is widely patent. LA, left atrium; LV, left ventricle; MEM, membrane; RA, right atrium; RV, right ventricle; RVOT, right ventricular outflow tract; VSD, ventricular septal defect.

Cardiac Catheterization

The need for cardiac catheterization has diminished substantially with the development of echocardiography. Catheterization is indicated in specific clinical instances. In the newborn, there may be a need to define sources of pulmonary blood flow and associated cardiac anomalies not clearly defined by echocardiography. Although most patients with tricuspid atresia have large defects in the atrial septum, a restrictive interatrial communication may be present. In these patients, a balloon septostomy may be necessary to relieve any obstruction to egress of blood flow from the right atrium. Occasionally, a large atrial septal defect will become restrictive with time. A balloon septostomy in older patients will often be inadequate, necessitating a blade septostomy or, rarely, surgical intervention (14).

During catheterization, a venous catheter introduced through the groin can be manipulated easily from the right atrium into the left atrium. Indeed, because there is no direct communication from the right atrium to the right ventricle, advancing the venous catheter into the left atrium is the only available pathway. The catheter then can be manipulated easily into the left ventricle. If necessary, the catheter can be advanced, often with the help of a tip-deflector wire, into the posterior great artery, which arises directly from the left ventricle. This may be necessary especially in patients with associated D-transposition of the great arteries in whom the echocardiogram suggests obstruction into the posterior pulmonary artery. It is usually difficult to advance the catheter from the left ventricle into the right ventricle and then into the anterior great artery unless the VSD is large. Fortunately, clinical and echocardiographic findings usually obviate the need to enter the right ventricle and pulmonary artery during catheterization.

Hemodynamic data during the catheterization in infants will show that the right atrial pressure is slightly higher than the left atrial pressure (7). There is likely to be a prominent a wave in the right atrium, especially if the interatrial communication is restrictive. Left ventricular systolic and end-diastolic pressures are likely to be normal, although the end-diastolic pressure may increase in patients with large VSDs as the pulmonary vascular resistance drops and left heart volume overload develops. In patients with associated D-transposition of the great arteries, pulmonary arterial hypertension will be present if there is no pulmonary stenosis. It is especially important in these infants to determine whether there is obstruction through the VSD or at the infundibulum that will result in obstruction to systemic blood flow.

Oxygen saturation in the systemic venous return will be lower than normal as a result of diminished oxygen saturation in the systemic arterial blood. In the absence of associated pulmonary disease, oxygen saturation of pulmonary venous return will be normal, but because of the obligatory right-to-left atrial-level shunt, left atrial and left ventricular saturations will be diminished.

Cardiac catheterization may be indicated to determine the hemodynamics following palliative surgical intervention prior to consideration for the next operation. The most critical determination is that of pulmonary vascular resistance because the eventual plan is creation of a complete systemic venous to pulmonary arterial communication. For patients with decreased pulmonary blood flow who have undergone placement of a shunt, a catheter usually can be manipulated through the shunt into the pulmonary artery. If this is not possible, obtaining a pulmonary venous wedge pressure can accurately reflect pulmonary artery pressure. In patients who have undergone placement of a pulmonary artery band (usually type IIc), a catheter can be advanced from the left ventricle across the band into the pulmonary artery.

Cardiac catheterization might be especially helpful in patients with associated cardiac malformations, especially type III patients. In patients with associated congenitally corrected transposition of the great arteries and ventricular inversion, atresia of the tricuspid valve and a restrictive interatrial communication will result in symptoms of pulmonary venous congestion. It is important to determine pulmonary artery pressure and to define sources of pulmonary blood flow in more complex patients, such as those with associated truncus arteriosus, so that appropriate initial steps can be taken to optimize chances for successful subsequent surgeries.

Finally, in patients who have undergone an intermediate surgical procedure anastomosing the SVC to the pulmonary artery (bidirectional Glenn), a catheter must be introduced through a vein in the upper part of the body (i.e., internal jugular, subclavian, brachial) to enter the pulmonary artery. This maneuver is important to measure pulmonary artery pressure and to estimate pulmonary vascular resistance.

Angiocardiography

The diagnosis of tricuspid atresia can be confirmed at catheterization by performing a right atriogram or superior vena cava-gram that demonstrates absence of flow directly from the right atrium to the right ventricle. This type of angiographic study is rarely necessary, however. Angiography may be useful to define more fully the location and size of a VSD and the source of pulmonary blood flow (Fig. 38.6). Angiography occasionally can document a right ventricular cavity that is larger than that suggested by echocardiography. This difference is not likely to be of clinical significance, however. Because the size of the pulmonary arteries is important for the eventual systemic venous-to-pulmonary artery anastomosis, angiography may be important not only to evaluate pulmonary artery size but also to determine the presence or absence of pulmonary artery distortion that may have been caused by previous surgery. These distortions may be caused by aortopulmonary shunts created in patients with normally related great arteries and

restricted pulmonary blood flow (type Ia and Ib) or patients with d-transposition of the great arteries who have undergone pulmonary artery banding (type IIc).

Angiography may be particularly important in patients with more complex associated cardiac lesions (type III) to define associated anomalies such as anomalous pulmonary venous drainage or coarctation of the aorta. In older patients, especially those who have not yet undergone a more definitive palliation, angiography is extremely important to define the presence or absence of collateral arteries from the descending aorta supplying portions of the lungs. Patients who have undergone a complete systemic venous-to-pulmonary arterial anastomosis, especially if marginally increased pulmonary vascular resistance is present, may require angiography to determine whether collateral venous channels resulting in a functional right-to-left shunt are present (*infra vide*). Angiography in these patients must be obtained using a venous approach from the upper part of the body as described above.

Recent advances in CT and MR imaging have obviated many of the imaging issues that previously required angiography. Catheterization is mainly used for therapeutic rather than diagnostic reasons in the recent era.

Treatment

Patients with tricuspid atresia will undergo one or more surgical procedures to achieve the eventual goal of separation of the systemic and pulmonary circuits. Because of the single-ventricle physiology, separation of the circuits will ultimately include a complete systemic venous-to-pulmonary artery anastomosis with elimination of the right-to-left atrial level shunt. The goal of surgery in the newborn infant is to (a) provide pulmonary blood flow adequate to avoid extreme hypoxemia; (b) prevent pulmonary overcirculation and pulmonary hypertension, which can lead to left ventricular failure or pulmonary vascular disease; and (c) preserve pulmonary artery anatomy for later surgery.

Figure 38.6. Views of a left ventriculogram from an infant with tricuspid atresia type Ic. **A:** A left anterior oblique view demonstrating a dilated left ventricle. Note the dense opacification of both the aorta and the pulmonary artery. The arrowheads outline the VSD. The hypoplastic right ventricle is well seen. **B:** A right anterior oblique view of the same ventriculogram shown in (A). The large ventricular septal defect is outlined by arrowheads. Ao, aorta; LV, left ventricle; PA, pulmonary artery; RV, right ventricle.

If severe restriction to pulmonary blood flow is present at birth, an infusion of prostaglandin E_1 (0.025 to 0.1 mg/kg/min) will maintain patency of the ductus arteriosus and ensure adequate pulmonary blood flow until surgery can be performed. Intubation and mechanical ventilation may become necessary because of the potential apnea caused by prostaglandin in a small percentage of patients. Other side effects for which these patients must be monitored include seizures, fever, and hypotension resulting from peripheral vasodilation.

The newborn with tricuspid atresia and normally related great arteries will have either an aortopulmonary shunt or pulmonary arterial banding procedure if there is diminished pulmonary blood flow (types Ia and Ib). If there is no obstruction between the left ventricle and the pulmonary circulation (type Ic), initial palliative treatment is either pulmonary artery detachment and central shunting or a pulmonary artery band. Occasionally, a type I patient will have enough obstruction to pulmonary blood flow that overcirculation will not occur, but pulmonary blood flow will be adequate enough that an initial shunt is not necessary. These patients must be monitored closely for reduction in VSD size and resultant inadequate pulmonary circulation.

Various shunts have been used in the past to provide adequate pulmonary blood flow for types Ia and Ib. The initial aortopulmonary shunt to be developed was the Blalock-Thomas-Taussig shunt, which anastomosed the subclavian artery to the ipsilateral pulmonary artery in an end-to-side fashion (15). This shunt fell out of favor because of the difficulty in maintaining patency in the early postoperative period. Other shunts then were developed, including the Potts shunt (16) (creation of a window between the descending aorta and the distal left pulmonary artery [LPA]) and the Waterston shunt (17) (creation of a window between the ascending aorta and the proximal right pulmonary artery [RPA]). These latter two operations resulted in various complications, including distortion of the pulmonary arteries, congestive heart failure with subsequent left ventricular dysfunction, and pulmonary hypertension with subsequent development of pulmonary vascular disease. As surgical techniques improved, the modified Blalock-Thomas-Taussig shunt, using prosthetic material (e.g., Gore-Tex tube), became the procedure of choice. Although distortion of the pulmonary artery still can occur, the more serious complications of left ventricular dysfunction and pulmonary vascular disease are rarely seen. A central shunt, which interposes a prosthetic tube between the ascending aorta and the MPA through a sternotomy, occasionally is used.

In patients with D-transposition of the great arteries and no obstruction to pulmonary blood flow (type IIc), a pulmonary artery band will be necessary not only to prevent pulmonary overcirculation but also to eliminate pulmonary hypertension and possible pulmonary arteriolar damage. An additional important consideration in patients with associated transposition is the size of the VSD. If there is obstruction to flow into the transposed ascending aorta, the options are to try to enlarge the VSD directly or to create an anastomosis between the MPA and ascending aorta, similar to the procedure described by Damus (18), Kaye (19), and Stansel (20). In this operation, the MPA is anastomosed to the ascending aorta. The branch pulmonary arteries usually are detached from the MPA, and pulmonary blood flow is supplied by an aortopulmonary shunt. Left ventricular output then will flow both through the restrictive VSD into the transposed aorta and directly into the MPA and subsequently into the ascending aorta. Other more complex surgery may be necessary, depending on associated lesions, especially in type III patients. The exact surgery to be performed depends on the specific details of the cardiac anatomy.

In 1965, Glenn et al. (21) described an operation that created an anastomosis between the SVC and the distal RPA.

This operation was performed by detaching the SVC from the right atrium and the RPA from the MPA. The SVC and RPA then were anastomosed in an end-to-end fashion. In this situation, the RPA blood flow was composed entirely from the systemic venous return, but the LPA was supplied by mixed systemic and pulmonary venous return traveling through the heart into the MPA. This operation was used successfully for many forms of cyanotic heart disease, including tricuspid atresia. The Glenn anastomosis was an attractive surgical option because it provided enough pulmonary blood flow to prevent severe hypoxemia and its consequences and, because the flow into the RPA was venous, there was no risk of developing pulmonary hypertension. Patients undergoing a Glenn anastomosis still had persistent right-to-left shunting from the inferior vena caval blood and its associated potential complications. Additionally, some patients develop pulmonary arteriovenous malformations many years after the Glenn shunt, which then worsens the cyanosis.

In 1971, Fontan and Baudet (22) described an operation that resulted in complete separation of the systemic and pulmonary circuits. The superior vena caval blood was directed to the RPA (Glenn shunt), and the right atrial appendage was anastomosed to the LPA system, which directed all the inferior vena caval blood into the LPA, interposing an aortic homograft valve. The atrial septal defect then was closed, completing separation of the systemic venous return and the pulmonary venous return (Fig. 38.7A). A similar operation was described by Kreutzer et al. (23) in which the right atrium was anastomosed directly to the MPA with an interposed semilunar valve. In this procedure, the branch pulmonary arteries remained in continuity with each other.

It has become convention to refer to any operation that reroutes systemic venous return into the pulmonary arteries without passing through a ventricle as a Fontan operation or its modifications. Over the ensuing years, completion of a Fontan procedure has become the eventual goal for all patients with tricuspid atresia. In 1978, Choussat et al. (24) described 10 criteria for optimal results following the Fontan procedure. These criteria included (a) age at operation between 4 and 15 years; (b) the presence of normal sinus rhythm; (c) normal systemic venous connections; (d) normal right atrial size; (e) normal pulmonary arterial pressure (mean ≤ 15 mm Hg); (f) low pulmonary vascular resistance (4 Woods units/m²); (g) adequate-sized pulmonary arteries with diameter $\geq 75\%$ of the aortic diameter; (h) normal left ventricular ejection fraction ($\geq 60\%$); (i) an absence of mitral valve insufficiency; and (j) absence of complicating factors from previous surgeries, such as pulmonary artery distortion. Today, the classic Fontan procedure is rarely, if ever, performed, but many modifications can accomplish the same physiologic result. Additionally, some of the criteria listed by Choussat et al. are no longer considered necessary to achieve an excellent result. Whereas it is still important that pulmonary vascular resistance (and therefore pulmonary pressure) is low, a modified Fontan procedure is routinely done in children younger than 4 years of age, many of whom had abnormal systemic venous connections. Diminished left ventricular function and the presence and degree of mitral valve insufficiency have become only relative contraindications. Nevertheless, with the exception of the age and size of the patient, a better outcome can be expected if all or most of the other criteria listed above are present.

Creation of the physiology of a Fontan procedure or one of its modifications results in marked changes in systemic venous hemodynamics. In the best of circumstances, the systemic venous or right atrial pressure rises significantly, equaling the mean pulmonary artery pressure. This sudden change in right-sided hemodynamics can cause early complications, such as persistent pleural effusions, in part because of altered lymphatic drainage. If the pulmonary vascular resistance is

Figure 38.7. Diagrams depicting the original Fontan procedure and two subsequent modifications. **A:** The original procedure included (i) SVC to RPA anastomosis (Glenn shunt) and anastomosis of the right atrial appendage to the left pulmonary artery system directing IVC flow through a valved homograft, (ii) placement of a valved homograft at the IVS-RA junction, and (iii) closure of the atrial septal defect. **B:** Modified Fontan directing IVC flow through the lateral portion of the RA into the pulmonary artery system via an anastomosis to the underside of the RPA. The SVC flow is already directed into the RPA by a previous bidirectional Glenn shunt. **C:** Modification of the Fontan procedure using an extracardiac conduit. Ao, aorta; IVC, inferior vena cava; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RPA, right pulmonary artery; RV, right ventricle; SVC, superior vena cava.

elevated or there is any impediment to forward flow through the pulmonary vascular tree, filling of the left heart will be compromised, resulting in low cardiac output.

In many cardiac centers performing these kinds of operations, an intermediate step has been developed between the newborn physiology and the Fontan procedure. A bidirectional Glenn anastomosis creates a communication between the SVC and the RPA that allows blood to go both into the RPA and LPA (25) (Fig. 38.8). The inferior vena caval blood

continues to flow right to left at the atrial level. The bidirectional Glenn anastomosis has the advantage of providing an adequate amount of effective pulmonary blood flow, diminishing the volume load on the left ventricle and preventing distortion of the pulmonary artery. Depending on the anatomy of the branch pulmonary arteries (e.g., stenosis resulting from previous surgery), differential blood flow can occur which may have to be addressed at later surgical intervention. Indeed, some studies suggest differential flow occurs simply due to the physiology of the venous return from either side of the body, and this differential flow may affect interpretation of studies that evaluate surgical results (26).

At a later date, after the patient has accommodated to the partial change in physiology, a complete cavopulmonary anastomosis can be accomplished by directing the inferior vena caval blood into the pulmonary artery. This procedure usually is performed by creating a tunnel within the right atrium, directing the inferior vena caval blood into the pulmonary artery through an anastomosis on the underside of the RPA (Fig. 38.7B). The portion of the right atrium not included within the tunnel remains part of the pulmonary venous atrium. Some investigators believe that loss of energy can be minimized with careful attention to the details of the anastomosis and/or type of procedure such that the direction of flow into each pulmonary artery avoids sharp turns and obstructions, thereby optimizing the fluid dynamics (27,28). The total cavopulmonary anastomosis has an additional advantage over the classic Fontan procedure in that it eliminates the dilated systemic venous reservoir with elevated pressure (right atrium) in which the blood flow is sluggish, predisposing to the development of thrombus formation and arrhythmias, especially atrial flutter. This physiology also can be accomplished by using an external conduit directing the inferior vena caval blood into the right pulmonary without using any of the right atrium (Fig. 38.7C).

In the best of circumstances, the force with which blood flows through the right side of the heart will be less than normal. It is imperative, therefore, that any impediment be relieved as much as possible. Interventional catheterization techniques (angioplasty with or without stent implantation) may be useful in alleviating obstruction to forward flow secondary to pulmonary artery distortion. In some cases surgical

Figure 38.8. Pulmonary angiogram from a patient with tricuspid atresia who has undergone creation of a bidirectional Glenn anastomosis. The catheter was introduced through the internal jugular vein and superior vena cava (SVC). The tip is at the SVC-RPA junction. The pulmonary arterial tree is well visualized, and there is no distortion of the branch pulmonary arteries. LPA, left pulmonary artery; RPA, right pulmonary artery.

intervention might be necessary. The optimal timing of completion of a total cavopulmonary anastomosis is not established, but most investigators agree that earlier completion is better if circumstances permit. There is evidence that excessive volume overload on the left ventricle for a prolonged period can have detrimental effects on ventricular performance years later (29). In addition, patients having undergone completion of a total cavopulmonary anastomosis before 3 years of age were shown in one study to have better exercise tolerance up to 10 years after surgery than a group who underwent repair at a later age (30).

For patients having undergone a modification of Fontan procedure, arrhythmias can be particularly troublesome. It is important to try to maintain sinus rhythm. Depending on the exact type of surgical repair (e.g., intra-atrial baffling, external conduit, etc.), patients may have a greater propensity toward arrhythmias due to abnormalities in electrical dispersion (31). If appropriate drug treatment is unsuccessful, more aggressive therapy may be necessary. Electrophysiology study and catheter ablation may be helpful in controlling some tachyarrhythmias (32). However, because the right atrial wall thickness is considerably greater than in normal hearts, the success rate is lower than that in patients with normal anatomy and physiology. Surgical techniques to control arrhythmias, especially atrial flutter, have proven useful in patients with more recalcitrant problems.

For patients with marginally elevated pulmonary vascular resistance, a technique was developed to place a small fenestration between the systemic venous atrium and the pulmonary venous atrium. The presence of the fenestration allows a "safety valve" so that some flow can bypass the lungs and help to ensure adequate filling of the left ventricle. The disadvantage, of course, is that some degree of cyanosis will persist. If the hemodynamics allow, the fenestration may be closed in the early postoperative period (33) or later at cardiac catheterization (34).

Prognosis

Patients born with tricuspid atresia who have not undergone a surgical palliation have a 1-year survival rate as low as 10%, depending on the type of tricuspid atresia and associated lesions (7). Before the widespread use of the modified Fontan procedure, the likelihood of a patient born with tricuspid atresia surviving into young adulthood was still quite low (~50%). Today, the outlook is much improved. Patients who undergo complete separation of the pulmonary and systemic venous returns by a modified Fontan procedure have widely varying outcomes, depending on details of the preoperative hemodynamic status (35–37). The overall mortality rate of patients undergoing the Fontan procedure in recent series is between 7% and 11% (38–40); however, most of the larger series include patients with many forms of single-ventricle physiology, and so these results must be reviewed carefully for the outcome of patients with tricuspid atresia.

Although some patients undergoing a modified Fontan procedure have excellent outcomes, others develop major clinical complications, including development of collateral (both arterial and venous) vessels. Because of the elevated systemic venous pressure, it is not unusual for small venous channels from the right atrium or the venae cavae to dilate and create right-to-left shunting. If the amount of shunting is substantial, resulting in significant systemic desaturation, some of these channels can be occluded using catheterization techniques. Unfortunately, other channels are likely to develop unless the underlying physiology is corrected. On the other hand, systemic arterial collateral vessels may develop from the descending aorta. These collaterals communicate with the pulmonary arterial tree, and the flow from these vessels competes

with the low-pressure pulmonary blood flow created by the modified Fontan procedure. This can result in increased volume load on the left ventricle. The collateral artery can usually be occluded later at catheterization.

A particularly bothersome long-term complication that develops in some patients having undergone a Fontan procedure is protein-losing enteropathy (PLE) (41,42). The exact mechanism of this condition, which includes hypoproteinemias, ascites, and peripheral edema, is not known, but elevated mean pulmonary artery pressure preoperatively has been shown to increase the likelihood of development of PLE postoperatively (43). The marked change in right atrial pressure and subsequent disturbance in lymphatic drainage and hydrostatic pressure, however, are likely to be involved. Various treatment modalities, including administration of corticosteroids or heparin, have been tried with varying success (44–46). Because of hypoalbuminemia, administration of parenteral albumin and a diet including medium-chain triglycerides may be helpful. No treatment has been found to have long-term benefit.

Compared with the pre-Fontan condition, exercise tolerance is improved after surgery; however, exercise capacity is diminished in patients who have undergone a Fontan procedure or one of the modifications compared with normal (47,48). Even in patients who are asymptomatic at rest, there is compromise of the response to exercise. Causes for this decreased response include lack of a right ventricle, depressed left ventricular function, impaired chronotropic response, conduit obstruction, or abnormal pulmonary vascular resistance. Because of the compromise in right heart flow even in the best results, most cardiologists now recommend anticoagulation. In addition, afterload reduction using angiotensin-converting enzyme inhibitors is becoming more commonplace, especially in patients who have any degree of left ventricular dysfunction.

It remains to be seen whether operating on younger children who have experienced fewer years of chronic hypoxemia and left ventricular volume overload will have a better long-term prognosis than patients who were operated on between the mid-1970s and mid-1980s; this population of patients was older when they underwent the final Fontan modification.

Cardiac transplantation remains an option for patients with tricuspid atresia who either have such complex associated anatomy that conventional palliation is not likely to be successful or for those who had undergone palliation and have developed long-term complications. Transplant is the only option for patients with severe left ventricular dysfunction or PLE unresponsive to medical management.

TRICUSPID STENOSIS

Congenital tricuspid stenosis usually is associated with other anomalies, especially right ventricular outflow tract obstruction or atresia with secondary hypoplasia of the right ventricle (49). Some investigators differentiate tricuspid valvar stenosis from hypoplasia of the valve (50). In the former condition, the annulus may be relatively large, but the leaflets are thickened with commissural fusion and shortened chordae tendineae. In the latter condition, the valve annulus is small, and the leaflets and chordae may be diminutive but otherwise normal.

Isolated tricuspid stenosis is extremely rare. When described in adults, it is highly likely that this finding is secondary to rheumatic heart disease rather than being a congenital anomaly. Familial occurrences of tricuspid stenosis have been described (51).

Clinical manifestations of isolated congenital tricuspid stenosis resemble those seen in tricuspid atresia, and the two conditions may be difficult to differentiate, even with cardiac

catheterization (49). Not only is the clinical presentation similar in these two lesions, but the ECG in isolated tricuspid stenosis may demonstrate the typical left-axis deviation, right atrial enlargement, and prominent left ventricular forces typical for tricuspid atresia. Some investigators have suggested, therefore, that isolated tricuspid stenosis is merely a mild form of tricuspid atresia. Differentiating between the two is important because better options for surgical intervention may exist in patients with tricuspid stenosis compared with those with tricuspid atresia.

Early reports of tricuspid stenosis were made from autopsy examinations (52). The first description in a living patient reported clinical and catheterization data and reviewed previously published reports (53). Surgery has been attempted in some patients with mixed results. Infants requiring intervention are likely to have more severe lesions, and the results are likely to be worse (49). Older patients would be expected to fare better, with commissurotomy or valve replacement being the main option.

TRICUSPID VALVE INSUFFICIENCY

Isolated congenital tricuspid valve insufficiency, other than that associated with Ebstein anomaly, is rare. Various anatomic abnormalities of the tricuspid valve have been described, accounting for some of these cases. Tricuspid valve insufficiency also may be associated with other lesions, especially severe stenosis or atresia of the right ventricular outflow tract. In this situation, however, the tricuspid insufficiency, in all likelihood, is a secondary phenomenon. Occasionally, tricuspid valve insufficiency may occur with a structurally normal valve in the absence of associated lesions. Usually, there is a history of an intrauterine or perinatal event resulting in right ventricular and especially papillary muscle dysfunction (54).

Anatomic abnormalities resulting in tricuspid valve insufficiency have been well described. In some cases, one or more of the valve leaflets may show nodular thickening with shortened chordae tendineae and hypoplastic or absent papillary muscles (55,56). Although there may be no downward displacement of the valve leaflets and the leaflets themselves are not adherent to the right ventricular myocardium, some investigators believe this form of tricuspid valve dysplasia represents a mild form of Ebstein anomaly. Interestingly, similar nodules are often also found on the mitral valve, although mitral insufficiency is infrequent. Other structural abnormalities of the tricuspid valve have been described, including an isolated cleft of a valve leaflet and absence of valve tissue altogether with a relatively normal valve annulus (unguarded tricuspid orifice).

Patients who have isolated tricuspid valve insufficiency usually present in the newborn period but also may present later in infancy and childhood or even in adulthood. Age at presentation obviously depends on several factors, the most important of which is the degree of valve dysfunction, which may be exaggerated in a newborn in the presence of elevated pulmonary vascular resistance and particularly following a complicated perinatal course. In neonates and infants with severe tricuspid insufficiency, cyanosis and clinical findings of congestive cardiac failure appear early. Cardiac examination includes a pansystolic murmur loudest at the left lower sternal border, often with a precordial thrill.

The chest radiograph is likely to demonstrate marked cardiomegaly with diminished pulmonary vascular markings. The ECG is likely to be relatively unhelpful, although in cases with a perinatal insult, ST-segment depression may be prominent in the anterior precordial leads (54). Echocardiography may or may not demonstrate dysplasia of the tricuspid valve, but Doppler and color flow examinations will provide a

definitive diagnosis while ruling out the presence of associated lesions. Careful ultrasound evaluation of the pulmonary valve is likely to differentiate between functional and anatomic atresia of the right ventricular outflow tract (55,56). Cardiac catheterization, therefore, is unlikely to be necessary. In the event it is undertaken, findings are likely to include elevated right atrial pressure with a right-to-left atrial-level shunt. Right ventricular systolic pressure may be elevated, but in the case of severe insufficiency, it may be normal. Angiocardiography will demonstrate dense opacification of the right atrium. The degree of pulmonary artery opacification will depend on whether the right ventricle can generate enough forward flow to open the pulmonary valve in the face of elevated neonatal pulmonary vascular resistance.

The prognosis for newborns with tricuspid insufficiency depends on the extent of valve dysfunction, associated cardiac lesions, and cause of the insufficiency. Resolution of neonatal tricuspid insufficiency has been described, presumably in patients with relatively normal tricuspid valve structure and insufficiency owing to papillary muscle dysfunction (54). Early attempts at surgical intervention have been largely unsuccessful. With improved surgical techniques, the prognosis is likely to be improved, but there are no reports of successes thus far in infants with *severe* tricuspid insufficiency attributable to valve dysplasia. For patients who survive the newborn period and live into childhood, adolescence, or adulthood, the surgical options are likely to be greater, with a higher likelihood of success.

UHL ANOMALY

In 1952, a report published by Uhl (57) described an unusual congenital cardiac malformation consisting of an almost total absence of the right ventricular myocardium, although this condition was described years earlier by Sir William Osler (58). Uhl anomaly, as it has come to be known, is extremely rare, and by 1979, <20 cases had been reported, each individually as a case report (59). Some investigators have suggested that this condition is related to other conditions that affect the right ventricular myocardium, such as arrhythmogenic right ventricular dysplasia (60). Although some cases of Uhl anomaly presented with clinical findings consistent with tricuspid valve insufficiency, tricuspid valve abnormalities have not been universally reported.

The typical anatomic findings of Uhl anomaly have been described on prenatal ultrasound examination (61). Ages at postnatal presentation ranged between 1 day and 57 years, with equal gender distribution. Because each of these patients was reported as an isolated case without much family history, there is nothing to suggest a specific inheritance pattern. Most patients were clinically cyanotic, and, except for the presence of an atrial septal defect or patent foramen ovale, other associated congenital heart defects were rare. Clinical signs of right heart failure are almost universally present.

At physical examination, along with cyanosis, hepatomegaly is often present as well as jugular venous distension with a dominant "a" wave. Surprisingly, in view of gross right ventricular dilation found at autopsy, the precordium usually is described as being quiet, and peripheral pulses often are diminished in amplitude. Cardiac auscultation usually reveals a decrease in the intensity of the heart tones, especially the first heart sound. A typical pansystolic murmur of tricuspid insufficiency may be present, but patients may have other nonspecific murmurs or indeed no murmur at all.

Electrocardiography usually shows prominent right atrial enlargement with P waves often larger than the markedly diminished QRS amplitude, especially in the right precordial

leads. The chest radiograph demonstrates cardiomegaly, often of impressive degree, and normal to diminished pulmonary vascularity, often leading to the mistaken diagnosis of Ebstein anomaly of the tricuspid valve.

Echocardiography demonstrates marked dilation of the right-sided cardiac chambers. Although detailed echocardiographic investigation of Uhl anomaly using present-day instrumentation has not been described, an important finding is the presence of the tricuspid valve leaflets arising appropriately from the annulus, differentiating this lesion from Ebstein anomaly. Recently, newer techniques have been used to help characterize this lesion and to aid in planning treatment (62).

At cardiac catheterization, a typical finding is the similarity of pressure wave contours obtained from the pulmonary artery, right ventricle, and right atrium. The right atrial wave is dominant. There is usually systemic desaturation. Endocardial potentials, if recorded during catheterization, show normal transition between the ventricular and atrial complexes, helping to rule out Ebstein anomaly (59). Angiocardiology demonstrates dilated right cardiac chambers with delayed filling of the pulmonary artery and also may demonstrate a small right-to-left atrial shunt.

Although a few patients have been described who lived into adulthood, most patients die in infancy or childhood. The typical pathologic finding is the markedly dilated right ventricle, which is described as parchment-like. Histologically, the endocardium is thickened, and there are few if any true myocardial cells in the right ventricular free wall. Indeed, the right atrial wall may be thicker than the right ventricular anterior wall. The tricuspid valve arises normally from a dilated valve annulus and may be dysplastic but is not displaced into the right ventricular cavity as is typical for Ebstein anomaly.

Medical management has been of limited value. Various surgical procedures have been performed, including atrial septal defect closure, Potts anastomosis, and Glenn anastomosis. Most attempts at surgical intervention have failed to prolong life to any extent. However, procedures that create total cavopulmonary anastomosis and right ventricular exclusion, with or without resection of the dilated right ventricular anterior wall, have resulted in survival into later years (63–65). Although this lesion is extremely rare, at least one patient has undergone successful heart transplantation (66) and it has been considered in others (67). This form of treatment seems to be an option for long-term survival in symptomatic patients with findings of Uhl anomaly.

Ebstein's Anomaly, Congenital Tricuspid Valve Regurgitation, and Dysplasia

Sameh M. Said ■ Joseph A. Dearani

EBSTEIN'S ANOMALY

History

Wilhelm Ebstein (1836–1912) who was a German physician, described in a report titled, “Concerning a very rare case of insufficiency of the tricuspid valve caused by a congenital malformation” in 1866 the unusual cardiac findings in a 19-year-old laborer who had died of cyanotic heart disease (1). He accurately described the characteristic anatomic and the hemodynamic abnormalities of Ebstein anomaly (Fig. 39.1). By 1950, only three case reports of this anomaly had been published.

Prevalence

Ebstein's anomaly is a rare congenital heart defect, which occurs in about 1/200,000 live births. It accounts for almost 1% of all cases of congenital heart disease (2,3).

Pathologic Anatomy

Normally, the tricuspid valve (TV) has three leaflets: anterior, inferior (posterior), and septal. The leaflets of the TV develop equally from the endocardial cushion tissues and the myocardium (7). The leaflets and tensile apparatus of the atrioventricular (AV) valves are formed by a process of delamination of the inner layers of the inlet zone of the ventricles. In Ebstein's anomaly, delamination of the TV leaflets fails to occur, but the mechanism is not entirely understood.

Ebstein's anomaly is a malformation of the TV and right ventricle (RV) characterized by (4):

1. Adherence of the septal and inferior leaflets to the underlying myocardium (failure of delamination)
2. Downward (apical) displacement of the functional annulus (septal > inferior > anterior)
3. Dilation of the “atrialized” portion of the RV, with variable degrees of thinning of the free wall
4. Redundancy, fenestrations, and tethering of the anterior leaflet
5. Dilation of the right AV junction (true tricuspid annulus) (5,6)

Tricuspid Valve

TV morphology in Ebstein's anomaly is highly variable. The leaflets are malformed and are attached to both the TV annulus and to the right ventricular endocardium.

It may be funnel shaped, incompetent, or rarely stenotic.

■ Leaflets:

- The anterior leaflet:
 - Usually large and is attached to the TV annulus.
 - Generally redundant and may contain several fenestrations (8) (Fig. 39.2A and B).

- Chordae tendineae generally are short and poorly formed.

- It may be severely deformed, so that the only mobile leaflet tissue is displaced into the right ventricular outflow tract (RVOT), where it may form a sail-like intracavitary curtain.

- The inferior and septal leaflet development is variable and most often rudimentary and may even be absent due to failure of the delamination process.
- Leading edges may be freely mobile with chordal and/or papillary muscular support, or may be tethered (adherent) to the endocardium.
- The apical displacement of the hinge point of the valve from the AV ring is shown in (Fig. 39.3) (7,8). The point of maximal displacement is at the commissure between the inferior and septal leaflets (11). In normal hearts, the downward displacement of the septal and posterior leaflets in relation to the anterior mitral valve leaflet is <8 mm/m² body surface area (8). The spectrum of the malformation in Ebstein's anomaly may range from only minimal displacement of the septal and inferior leaflets to an imperforate membrane or muscular shelf between the inlet and trabecular zones of the RV. The range of variability is infinite. Typical autopsy examples of Ebstein's anomaly are shown in Figures 39.4 and 39.5.
- TV annulus
 - There often is marked dilatation of the true TV annulus, which is not displaced, and a large chamber separating the true annulus from the functional RV is the “atrialized” portion of the RV(8) (Fig. 39.3).

Right Coronary Artery

The right coronary artery (RCA) demarcates the level of the true annulus. The thin nature of the atrial and ventricular tissue at the level of the AV groove makes the RCA vulnerable to kinking or distortion during RV plication, annuloplasty procedure (Figure 39.6), or TV replacement.

Right Ventricle

- In Ebstein's anomaly, the RV is divided into two regions: the area involved with the malformation (i.e., the inlet portion) that is functionally integrated with the right atrium (RA), and the area that is not involved by the anomaly and consists of the other two components of the RV—the trabecular and outlet portions, which constitute the functional RV. The “atrialized” portion of the RV (i.e., the inlet component) can become disproportionately dilated and may account for more than half of the RV volume instead of the usual one-third of the total right ventricular volume (Fig. 39.7A and B).
- The majority (>2/3) of hearts with Ebstein's anomaly have RV dilatation. Dilatation often involves not only the atrialized inlet portion of the RV but also the functional right ventricular apex and outflow tract. In some cases,

Figure 39.1. Figure from Ebstein's original case report. The RA and RV are shown opened along the right border beginning at the superior vena cava. A, RA; B, RV; b, valve; I, rudimentary septal leaflet of TV with its chordae tendineae, which insert on the endocardium of the ventricular septum; r, opening through which one can get into the right conus arteriosus, and in the opposite direction, one can get into the sac that is formed by membrane h, h', and posterior part of endocardium of ventricular septum o. (From Mann RJ, Lie JT. The life story of Wilhelm Ebstein (1836–1912) and his almost overlooked description of a congenital heart disease. *Mayo Clin Proc* 1979;54:197–204, used with permission of the Mayo Foundation for Medical Education and Research.).

right ventricular dilatation is so marked that the ventricular septum is deviated leftward, compressing the left ventricular chamber (8). In such cases, the short-axis view demonstrates a circular RV and a D-shaped or crescent-shaped left ventricle (LV). In extreme cases, episodic left ventricular outflow tract obstruction (LVOTO) can occur (Fig. 39.8).

Figure 39.2. A,B: Ebstein's heart: marked fenestrations, and tethering of the TV anterior leaflet. (Used with permission of the Mayo Foundation for Medical Education and Research.)

Classifications

- A. Based on the echocardiographic appearance, Ebstein's anomaly can be classified as mild, moderate, or severe (9) according to:
 - Extent of the apical displacement of the TV leaflets
 - Degree of tricuspid regurgitation (TR)
 - Degree of RV dilatation and dysfunction
- B. Four types of Ebstein's anomaly were proposed based on the anatomic findings during surgery (10) (Table 39.1). This is our preferred approach, which is to describe the exact anatomy of each of the involved structures of the heart as visualized at operation. This nomenclature system emphasizes characteristics that surgeons find important when considering repair of the TV. In general, classification systems of Ebstein's anomaly are difficult since there are infinite variations in the anatomy and no two hearts are alike.
- C. In 1988, Carpentier et al. (11) proposed the following classification of Ebstein's anomaly (Fig. 39.9):
 - Type A: the volume of the true RV is adequate
 - Type B: a large atrialized component of the RV exists, but the anterior leaflet of the TV moves freely
 - Type C: the anterior leaflet is severely restricted in its movement and may cause significant obstruction of the RVOT
 - Type D: almost complete atrialization of the ventricle except for a small infundibular component.
- D. Celermajor et al. (12) described an echocardiographic grading score for neonates with Ebstein's anomaly, the Great Ormond Street Echocardiography (GOSE) score, with grades 1 to 4. The ratio of the combined area of the RA and atrialized RV is compared to the functional RV and left heart. This classification is particularly helpful with neonatal Ebstein's anomaly.
 - Grade 1: ratio <0.5
 - Grade 2: ratio of 0.5 to 0.99
 - Grade 3: ratio of 1.0 to 1.49
 - Grade 4: ratio ≥ 1.5

Genetic Factors

There are heterogeneous genetic factors in Ebstein's anomaly. Case-control studies suggest genetic, reproductive, and environmental risk factors (e.g., the anomaly is more common in twins, in those with a family history of congenital heart disease, and in those with maternal exposure to benzodiazepines) (13). Most cases are sporadic; familial Ebstein's anomaly is rare. In a genetic study of 26 families with Ebstein's anomaly, 93

Figure 39.3. Top: Normal TV with anterior, posterior, and septal leaflets in one plane. Middle: TV in right-sided Ebstein's anomaly showing displacement of posterior and septal leaflets; maximal displacement is at the crux of the posterior and septal leaflets. Bottom: TV in left-sided Ebstein's anomaly; the displacement of leaflets is similar to that in the right-sided anomaly. (From Anderson KR, Zuberbuhler JR, Anderson RH et al., Morphologic spectrum of Ebstein's anomaly of the heart: a review. *Mayo Clin Proc* 1979;54(3):174–180, with permission.)

of 120 first-degree relatives were evaluated (14). No case of the anomaly was found, but two first-degree relatives had ventricular septal defects (VSDs), and another, who died at seven months, was said to have had congenital heart disease. Rare cases of cardiac transcription factor NKX2.5 mutations, 10p13-p14 deletion, and 1p34.3-p36.11 deletion have been described in the anomaly (15,16). Recently, Postma et al. (17) reported the results of a mutational analysis in a cohort of 141 unrelated probands with Ebstein anomaly. Eight were found to have a mutation in the gene MYH7 and six of the eight patients also had left ventricular noncompaction. This may warrant genetic testing and family evaluation in this subset of patients.

Associated Cardiac Defects

The most common associated cardiac defects include (18,19):

- Interatrial septal defects:
 - Patent foramen ovale (PFO) or an atrial septal defect (ASD), mostly secundum, is present in 80% to 94% of the patients (20).
- VSD with or without pulmonary atresia.
- RVOT obstruction
 - Due to structural abnormalities (pulmonic valve stenosis or pulmonary atresia), branch pulmonary artery stenosis, and, rarely, the displaced TV.
- Patent ductus arteriosus.

Figure 39.4. Marked cardiomegaly caused by right-sided chamber dilatation in a 67-year-old man with severe Ebstein's anomaly, with normal heart at right for comparison (anterior view). (Used with permission of the Mayo Foundation for Medical Education and Research.)

Figure 39.5. Severe Ebstein's malformation of TV (*four-chamber view*) showing marked downward displacement of shelf-like posterior leaflet with attachment to underlying free wall by numerous muscular stumps (*arrows*), markedly dilated atrialized portion of right ventricle (ARV), small functional portion of RV, leftward bowing of ventricular septum, and marked dilatation of RA. LA, left atrium; LV, left ventricle. (Used with permission of the Mayo Foundation for Medical Education and Research.)

- Coarctation of the aorta.
- One or more accessory conduction pathways are present in up to 15% to 20% of patients with Ebstein's anomaly, predisposing patients to arrhythmias. The majority of these pathways are located around the orifice of the malformed TV (7,21).

Figure 39.6. Pathologic specimens showing: the close relation between the RCA and the TV annulus. RCA (*arrow*) can be easily kinked (*dashed arrow*) during TV repair procedure. RCA, right coronary artery; TV, tricuspid valve. (Used with permission of the Mayo Foundation for Medical Education and Research.)

- Left sided heart lesions:
 - Diastolic and systolic dysfunction
 - Mitral valve prolapse
 - Accessory mitral valve tissue
 - Subaortic stenosis
 - Bicuspid or atretic aortic valve
 - Muscle bands of the LV
 - Myocardial changes resembling left ventricular non-compaction (22)

We recently reported features resembling noncompaction in three patients with Ebstein's anomaly (25). Since then, we have analyzed 106 consecutive patients who had Ebstein's anomaly and found left-sided heart abnormalities in 39%; 18% of these patients had left ventricular dysplasia resembling noncompaction (21).

- Congenitally corrected transposition of the great arteries (cc-TGA):

Most patients with cc-TGA have an abnormal systemic AV valve (morphologic TV) that fulfills the criteria for Ebstein's anomaly in 15% to 50% of cases (23). The Ebsteinoid displacement (Fig. 39.10) of the TV into the morphologic RV is different from the classic right-sided Ebstein malformation in that there is usually a lack of atrialization of the RV free wall (24). In addition, when functioning at lower pulmonary pressures after a double-switch procedure, the regurgitation is reduced markedly; that is, it tends to be a high-pressure regurgitant valve rather than a low-pressure regurgitant valve (25). The morphological RV (systemic ventricle) is rarely dilated in cc-TGA.

Pathophysiology

Due to the wide spectrum of anatomic severity, there is a wide spectrum of pathophysiology and associated symptoms. The functional impairment of the RV and TV regurgitation retard forward flow of blood through the right side of the heart. In addition, during contraction of the atrium, the atrialized portion of the RV balloons out and acts as a passive reservoir, decreasing the volume of ejected blood. The overall effect on the RA is dilatation, increasing the size of an interatrial communication. TR increases with progressive annular dilatation. Associated heart disease in Ebstein's anomaly has an additional detrimental effect on cardiopulmonary physiology. Symptomatic neonates have massive cardiac enlargement with associated hypoplasia of the lungs. Due to the absence of forward flow from the ineffective RV, there can be physiologic pulmonary atresia, and the child is dependent on ductal patency for survival. All systemic venous return must pass from right to left, across a PFO or ASD. The enormous capacitance of the RA and the inefficiency of the RV prevent adequate filling of the LV. LV output also is compromised in sick neonates, and these neonates are severely cyanotic and acidotic. Those with less severe atrialization of the RV may have adequate pulmonary blood flow that will further improve with the decrease in pulmonary vascular resistance. At the other end of the spectrum, there may be only a mild degree of cyanosis, which may not be noted until adult life and may result in few, if any, symptoms.

Clinical Presentation

Presentation varies widely and can range from the severely symptomatic neonate to an incidental finding in an

Figure 39.7. A: Ebstein's heart with marked dilatation of the RV. B: Severe apical displacement of the TV apparatus is shown (*double-headed arrow*), the RV in Ebstein's anomaly is divided into two regions: the RV proper and the atrialized portion, which can become disproportionately dilated and may account for more than half of the RV volume in extreme cases instead of the usual one-third of the total right ventricular volume. RA, right atrium; LA, left atrium; LV, left ventricle; RV, right ventricle; RAA: right atrial appendage; aRV, atrialized right ventricle. (Used with permission of the Mayo Foundation for Medical Education and Research.)

octogenarian. In general, symptoms are related to the anatomic severity. Patients with mild apical displacement and normal function of the TV may remain asymptomatic for years (26). In the presence of marked tricuspid leaflet displacement or abnormal leaflet attachment and severe valvular regurgitation, patients will have elevated right atrial pressure, and significant right-to-left interatrial shunting with arterial desaturation. The anomaly may be fatal shortly after birth if severe heart failure is present (15).

Figure 39.8. Ebstein's heart showing marked dilatation of the RV. In extreme cases, episodic LVOTO can occur with marked interventricular septal shift. RA, right atrium; RV, right ventricle; LV: left ventricle. (Used with permission of the Mayo Foundation for Medical Education and Research.)

In a review of 220 patients with Ebstein's anomaly, the most common presentation varied with age at presentation (10):

- Fetuses—an abnormal routine prenatal scan (86%)
- Neonates—cyanosis (74%)
- Infants—heart failure (43%)
- Children—an incidental murmur in children (63%)
- Adolescents and adults—arrhythmia (42%), decrease exercise tolerance, fatigue, or right-sided heart failure.

Early age at presentation frequently was associated with other cardiac lesions, particularly pulmonary stenosis or atresia. Ebstein's anomaly is a common lesion referred for fetal echocardiography because severe forms may lead to cardiomegaly, hydrops, and tachyarrhythmias (27,28).

Symptoms

CYANOSIS AND HEART FAILURE

- From significant TR
- May appear soon after birth, because of high pulmonary vascular resistance (10).
- Often improves as pulmonary vascular resistance decreases.

EXERTIONAL DYSPNEA, FATIGUE, CYANOSIS, AND PALPITATIONS

- May occur at a later age
- May recur; and may be insidious in onset.

PALPITATIONS

- Due to atrial tachyarrhythmia
- Present in 20% to 30% of cases (10,29)
- Some of these arrhythmias may be due to Wolff-Parkinson-White syndrome (WPW).

PARADOXICAL EMBOLIZATION

- In the presence of an interatrial communication, patients with Ebstein's anomaly are at risk for paradoxical embolization, brain abscesses, and sudden death.

TABLE 39.1 Types of Ebstein's Valve Based on the Anatomic Findings During Surgery

Type	Anterior Leaflet		Posterior Leaflet	Septal Leaflet	Atrialized RV Chamber Size
	Size	Mobility			
I	Larger	Mobile	Apically displaced, dysplastic, or absent.		Varies from relatively small to large.
II	Relatively small and displaced in a spiral fashion toward the apex.				Moderately large.
III		Restricted motion Shortened, fused, and tethered chordae. Direct insertion of papillary muscles into the anterior leaflet is frequently present.	Displaced, dysplastic, and usually not reconstructible.		Large
IV		Severely deformed Few or no chordae. Direct insertion of the papillary muscles into the leading edge of the valve is common.	Typically dysplastic or absent	Represented by a ridge of fibrous material descending apically from the membranous septum.	Nearly the entire RV cavity is atrialized. TV tissue is displaced into the RVOT and may cause obstruction of blood flow (functional tricuspid stenosis).

Physical Examination

Findings vary with the severity of pathology and the magnitude of right-to-left interatrial shunting.

- Murmur and click; commonly mistaken for mitral valve prolapse (11).
- Cyanosis
 - May be severe in infants.
 - Mild in older children.
 - Digital clubbing will depend on the degree of cyanosis (30).
- Prominent “a” wave in the distended jugular veins.
- Hepatomegaly:
 - Represents passive hepatic congestion resulting from TR and elevated right atrial pressure.
 - Hepatomegaly becomes pulsatile due to systolic expansion of the liver.
- Palpable prominent diffuse apical impulse
- Systolic thrill at the left lower sternal border.
- Widely split first and second heart sounds, resulting from right bundle branch block.
- A prominent S3 and/or a loud S4 give the impression of multiple heart sounds (triple or quadruple gallop).
- A systolic murmur
 - From TR
 - Increases in intensity with inspiration and may be associated with a mid-diastolic murmur due to high diastolic flow volume across the tricuspid annulus.
 - May be very soft or absent in adults because the low velocity of to- and-fro flow and rapid equalization of pressure across the TV does not result in blood flow turbulence.

- The jugular venous pulse rarely shows a large V wave despite severe regurgitation of the TV because the large RA engulfs the increased volume.

Diagnostic Evaluation

Chest Radiography

The cardiac silhouette varies from almost normal to a markedly enlarged globe-shaped heart with a narrow waist (Fig. 39.11) similar to that seen with pericardial effusion. The vascular pedicle is narrow because the pulmonary trunk is not border forming and the ascending aorta, with rare exception, often is small and inconspicuous or absent. Symptomatic neonates can have massive heart size (Fig. 39.12) and outcome is poor if the cardiothoracic ratio is >0.65 . The infundibulum either straightens the left cardiac border or forms a convex border. The most consistent and dramatic feature is the enlarged right atrial silhouette; this is seldom normal even if the cardiac silhouette is otherwise normal. Lung fields may be normal or decreased due to hypoplasia from severe cardiomegaly.

Electrocardiography

Ebstein's anomaly may be diagnosed using the electrocardiogram. It is rarely normal even with a mild anomaly. The major physiologic changes include the following (31) (Fig. 39.13):

- Intra-atrial conduction disturbance including PR interval prolongation and tall P waves.
- Right bundle branch block

Figure 39.9. Carpentier classification: Type A = minor anomaly: the ARV is small. Type B = intermediate: the displacement of the septal leaflet is 2 to 3 cm, the ARV is normally contracting. Type C = severe form: the septal leaflet is severely displaced, the posterior leaflet is adherent to the ventricular wall or absent, the ARV is huge with hypo or akinetic motion. Type D = tricuspid sac: the leaflet tissue, even the anterior one is adherent to the RV wall. The contractility of the RV is globally impaired. (From Chauvaud S, Carpentier A. Ebstein's anomaly: the Broussais approach. *Multimedia Manual of Cardiothoracic Surgery (Internet)* June 26, 2008, with permission.)

Figure 39.10. Ebsteinoid displacement of the TV (*inset*) in congenitally corrected transposition of great arteries (cc-TGA). This is different from the typical right-sided Ebstein TV. There is little if any atrialization of the RV free wall in cc-TGA. (Used with permission of the Mayo Foundation for Medical Education and Research.)

Figure 39.11. Chest radiograph: of a patient who had Ebstein's anomaly with severe TR and a small ASD before TV surgery. This typical image shows cardiomegaly, a narrow waist, and a cardiothoracic ratio of 0.56. (Used with permission of the Mayo Foundation for Medical Education and Research.)

- WPW preexcitation (Fig. 39.14)
- Supraventricular tachycardia
- Atrial flutter or fibrillation
- Arrhythmogenic atrialized RV
- Deep Q waves in leads V_{1-4} and in inferior leads

Complete AV block is rare but first-degree AV block occurs in 42% of patients due to right atrial enlargement and the

Figure 39.12. Chest radiograph: of a neonate with Ebstein's anomaly showing massive cardiomegaly. (Used with permission of the Mayo Foundation for Medical Education and Research.)

structural abnormalities of the AV conduction system (32). The AV node may be compressed but is in the normal location. Apical displacement of the septal leaflet is associated with discontinuity of the central fibrous body and the septal AV ring with direct muscular connections, creating a substrate for accessory pathways and pre-excitation (33).

More than one accessory pathway is present in 6% to 36% of cases (34); most of them are located around the orifice of the malformed TV (35). It is essential to correctly identify and treat these accessory pathways to prevent sudden cardiac death. Paroxysmal tachyarrhythmias in Ebstein's anomaly are based on typical, fast-conducting AV accessory pathways with both antegrade and retrograde conduction properties in most patients (37). In addition, wide QRS tachycardia over a septal accessory AV pathway, ventricular tachycardia, or flutter, as well as ectopic atrial tachycardia, atrial flutter, and atrial fibrillation, can occur (36).

Atrial fibrillation and atrial flutter are most likely caused by secondary alterations of the right atrial myocardium (dilatation), or may occur postoperatively and related to the atriotomy scar resulting in an incisional atrial tachycardia (37).

Echocardiography

2-D echocardiography is the diagnostic test of choice (Fig. 39.15) (37). More recently, 3-D echocardiography is also being used as an adjunct for additional details about TV anatomy. It accurately evaluates the TV and the size and function of different cardiac chambers.

Apical displacement of the septal leaflet by at least 8 mm/m² body surface area is considered a diagnostic feature of Ebstein's anomaly (8). The presence of at least three accessory attachments of the leaflet to the ventricular wall confirms leaflet tethering that causes restricted motion of the leaflet (30). Marked enlargement of the RA and atrialized RV is present when the combined area of the RA and atrialized RV is larger than the combined area of the functional RV, left atrium (LA), and LV in the apical 4-chamber view at end-diastole (15). Echocardiography allows assessment of the site and degree of TV regurgitation and the feasibility of valve repair (9). Ebstein's anomaly can be diagnosed in utero using fetal echocardiography in as early as the 18th week of pregnancy (38). Fetal echocardiography remains a challenge because of the small size of the heart, and it may be difficult to distinguish Ebstein's anomaly from pulmonary atresia or other causes of TR. Important features that can be determined echocardiographically and that can predict outcome in neonates with Ebstein's anomaly include the patency of the RVOT, and the GOSE score (39). The GOSE score, as described by Celermajer, is calculated in the four-chamber view to create a ratio of the combined areas of the RA and atrialized RV compared with the functional RV, LA, and the left ventricular areas. Patients who have the most severe GOSE score (grades 3 and 4) have a very poor prognosis (Table 39.2).

Cardiac Catheterization

This rarely is necessary, apart from preoperative coronary angiography in older patients. Pulmonary artery pressure usually is normal, although the right ventricular end-diastolic pressure may be elevated. Despite severe TV regurgitation, the right atrial pressure may be normal, especially with marked right atrial dilatation. Hemodynamic catheterization can also be performed in selected situations when there is left ventricular dysfunction and suspected elevated pulmonary artery pressures or elevated left ventricular end-diastolic pressure. This is particularly important if a bidirectional cavopulmonary anastomosis (BDCPA) is being considered.

Figure 39.13. ECG of a patient with severe Ebstein's anomaly showing the typical changes, with prolongation of the PR interval (226 ms), right bundle-branch block, and somewhat bizarre configuration of the QRS complex. (Used with permission of the Mayo Foundation for Medical Education and Research.)

Magnetic Resonance Imaging

Recently, cardiac magnetic resonance (CMR) imaging has emerged as another tool for evaluation of Ebstein's patients (Fig. 39.16). It provides quantitative measurement of right atrial and ventricular size and systolic function even in the presence of significant distortion of right ventricular anatomy. Axial imaging provides more reliable analysis and new expressions of disease severity, such as the atrialized right ventricular volume. The ability to create 3-D images (Fig. 39.17) may provide greater delineation of disease severity (40).

NATURAL HISTORY

It is not uncommon for Ebstein's anomaly to be undiagnosed until adulthood. The oldest patient in the Mayo surgical series was 79 years of age at time of diagnosis and subsequent surgery. However, late diagnosis is associated with reduced survival. The mean age of diagnosis in a study of the natural history of 72 unoperated patients, was 23.9 ± 10.4 years. In this group of patients, arrhythmias were the most common clinical presentation (51%) (41). The estimated cumulative overall survival rates were 89%, 76%, 53%, and 41% at 1, 10, 15, and 20 years of follow-up, respectively. Predictors of cardiac-related death on univariate analysis included: (a) cardiothoracic ratio of ≥ 0.65 , (b) increasing severity of TV displacement on echocardiography, (c) New York Heart Association (NYHA) class III or IV, (d) cyanosis, (e) severe TR, and

(f) younger age at diagnosis. In a multivariate model, younger age at diagnosis, male sex, cardiothoracic ratio of ≥ 0.65 , and the severity of TV leaflet displacement on echocardiography were predictors of late cardiac mortality.

MANAGEMENT

Neonatal Ebstein

Neonatal Ebstein's anomaly carries a poor prognosis, with reported survival of only 68% in one series (15). Surgery is required in the presence of heart failure or profound cyanosis. The surgical options include: (a) biventricular repair (Knott-Craig approach), (b) single ventricle pathway with right ventricular exclusion (Starnes' approach), and, rarely, (c) cardiac transplantation.

Biventricular Repair (Knott-Craig Approach)

This approach (Figure 39.18A–D) has been popularized by Knott-Craig (42) in which the TV is repaired and the atrial septum is partially closed. This repair is typically a monocusp type based on a satisfactory anterior leaflet (43). It is important in the early postoperative period to allow some right-to-left shunting across the atrial septum, especially in the presence of elevated pulmonary vascular resistance and right ventricular dysfunction. Routine right atrial reduction is important to reduce the size of the markedly enlarged heart to allow room for the lungs.

Figure 39.14. ECG of a patient with severe Ebstein's anomaly: showing sinus rhythm with pre-excitation (Wolf-Parkinson-White syndrome). (Used with permission of the Mayo Foundation for Medical Education and Research.)

Figure 39.15. Example of an echocardiogram (four-chamber view, apex down): of a patient with severe Ebstein's anomaly showing a grossly displaced septal leaflet (arrow). The anterior leaflet is severely tethered and nearly immobile. The functional RV is small. RV, right ventricle; aRV, atrialized right ventricle. LA, left atrium. LV, left ventricle; RA, right atrium. (Used with permission of the Mayo Foundation for Medical Education and Research.)

Postoperative care in these patients is challenging, and delayed sternal closure should be performed liberally. Inhaled nitric oxide may be helpful to decrease the pulmonary vascular resistance. Early arterial desaturation is not uncommon. Peritoneal dialysis catheters are helpful to ensure complete decompression of the abdomen. Although early mortality is high (about 25%), the intermediate outcome appears to be promising. In 2007, Knott-Craig et al. (44) reported their experience with 27 neonates and young infants. Associated anatomic or functional pulmonary atresia was present in 18 neonates, while VSDs, hypoplastic branch pulmonary arteries, and small LV were each present in three neonates. Biventricular approach was performed in 25 neonates with tricuspid repair in 23 of them. Survival to hospital dismissal was 74% with no late mortality. The median follow-up was 5.4 years with a maximum of 12 years. Despite high early mortality compared to many other neonatal anomalies corrected in the first month of life, these results have become a benchmark for a very difficult problem.

Right Ventricular Exclusion

■ Starnes Approach (Fig. 39.19)

Starnes et al. (45) pioneered the right ventricular exclusion approach, which involves: (a) fenestrated patch closure of the TV orifice, (b) enlarging the interatrial communication, (c) right atrial reduction, and (d) placing a systemic-to-pulmonary artery shunt. This approach is particularly useful when there is anatomic RVOT obstruction. Right ventricular decompression is required as it passively fills from Thebesian venous drainage;

this is usually accomplished with a 4- to 5-mm punch fenestration in the TV patch (46,47). This allows progressive involution of the enlarged, dysfunctional RV, which will be helpful at the time of Fontan completion. If the pulmonary valve is not competent, this will lead to right ventricular distension and in these situations, ligation or closure of the main pulmonary artery is required. Significant right ventricular dilatation can lead to left ventricular dysfunction, and the above mentioned issues must be considered at the time of initial surgery in order to optimize Fontan candidacy down the road.

■ Modified Starnes Repair (Total Ventricular Exclusion)

Sano et al. (48) modified the Starnes single-ventricle approach by performing a total right ventricular exclusion in which the free wall of the RV is resected and closed primarily (Fig. 39.20) or with a polytetrafluoroethylene patch (51). This simulates a large right ventricular plication, which may improve the left ventricular filling and provide adequate decompression to the lungs and LV.

The postoperative care is similar to any shunt-palliated patient with a univentricular heart. The primary goal is to optimize systemic perfusion while obtaining adequate oxygenation. Delayed sternal closure and peritoneal drainage also are helpful. Close surveillance is required between the first and second stage procedure (BDCPA), which usually is performed between 3 and 6 months of age.

Reemtsen et al. (49) reported the results of the single-ventricle pathway in 16 neonates; two patients underwent TV repair, one patient had heart transplantation, 10 patients had a right ventricular exclusion procedure with a fenestrated TV patch, and three patients had a right ventricular exclusion with a nonfenestrated patch. Operative survival was 80% in those with a fenestration versus 33% without. All survivors had a successful BDCPA (second stage), and three patients had Fontan completion.

Cardiac Transplantation

With the improved results of the biventricular and single ventricle approaches, transplantation rarely is performed in the current era. Cardiac transplantation remains an option in the most severe forms of Ebstein's anomaly, particularly when there is significant left ventricular dysfunction. Scarcity of organ donors and the side effects of immunosuppression are the main limitations. The availability of smaller ventricular

TABLE 39.2 Mortality Risk by GOSE Score

GOSE Score	Ratio	Mortality
1–2	<1.0	8%
3 (acyanotic)	1.1–1.4	10% early, 45% late
3 (cyanotic)	1.1–1.4	100%
4	>1.5	100%

GOSE 1: <0.5, GOSE 2: 0.5–1.0, GOSE 3, 1.1–1.4, GOSE 4: >1.5.

Cardiac magnetic resonance imaging and the assessment of ebstein anomaly in adults. *Am J Cardiol* 2011;107(5):767–773, Epub 2011 Jan 19, with permission from Elsevier.)

support devices and advances in neonatal extracorporeal membrane oxygenation have provided mechanical support options in the perioperative period for these infants undergoing conventional operation.

Children and Adults

Medical

Regular congenital cardiology evaluations for patients with Ebstein's anomaly are essential. Bacterial endocarditis prophylaxis may be required in the presence of prosthetic materials or patches that were used for the repair. Recommendations for physical activity are summarized by Task Force 1 on Congenital Heart Disease. In mild Ebstein's anomaly, with nearly normal heart size, and in absence of arrhythmias, athletes can participate in all sports. However, in severe Ebstein's anomaly, activity is restricted unless it has been optimally repaired with near normal heart size and no arrhythmias. Although rare in the current era, those who are not candidates for surgery are treated with standard heart failure regimens.

Angiotensin-converting enzyme inhibitors have unproven efficacy in cases of right-sided failure, but they are used frequently as part of a heart failure regimen. Individualized management of arrhythmias with medical treatment combined with operative or catheter-based intervention is recommended.

Catheter Ablation

Patients with tachyarrhythmias should undergo electrophysiologic evaluation with mapping and radiofrequency ablation of accessory pathways. The success rate of catheter ablation in Ebstein's patients is lower than in those with structurally normal hearts, and there is an increased risk of recurrence (50,51). Atrial tachyarrhythmias (fibrillation and flutter) are treated surgically at the time of operation.

Surgery

INDICATIONS FOR SURGERY

Apart from asymptomatic patients with no right-to-left shunting, and mild cardiomegaly, most patients require surgical intervention. The current indications for surgery include: presence

Figure 39.17. A,B: Three-dimensional reproduction of heart with Ebstein anomaly demonstrating: views of TV from (A) short axis and (B) axial imaging. aRV, atrialized right ventricle; fRV, functional right ventricle; LA, left atrium. LV; left ventricle; RA, right atrium; RVOT, right ventricular outflow tract. TVAL, TV anterior leaflet; TVPL, TV posterior leaflet; TVSL, TV septal leaflet. (Reprinted from Yalonetsky S, et al. Cardiac magnetic resonance imaging and the assessment of ebstein anomaly in adults. *Am J Cardiol* 2011;107(5):767–773. Epub 2011 Jan 19, with permission from Elsevier.)

of symptoms, cyanosis, and paradoxical embolization. Patients who have decreased exercise performance, progressive increase in cardiothoracic ratio, progressive right ventricular dilatation and dysfunction, onset or progression of arrhythmias, will benefit from surgical intervention. In the presence of class III or IV NYHA or significant symptoms, medical treatment has little to offer and the surgery will be the best chance for improvement. Echocardiographic assessment of the TV plays a key role in decision making regarding valve repair versus replacement. High probability of successful valve repair supports earlier operation.

PRINCIPLES OF SURGERY FOR EBSTEIN'S ANOMALY

The following principles are the goals of surgery: (a) closure of any intracardiac communications, (b) TV repair or replacement, (c) ablation of arrhythmias, (d) selective plication of the atrialized RV from apex to base, (e) reduction right atrio- plasty, and (f) repair of associated defects (e.g., closure VSD).

Tricuspid Valve Repair

The goal of operation is to obtain a competent TV, preserve right ventricular contractility, and to decrease the risk of late rhythm disturbances.

HISTORY

Repair of the TV was reported in 1959 in two patients who had Ebstein's anomaly; both died (52). In 1962, the TV was replaced, which was a successful operative intervention for the regurgitant valve (53). Several other methods for TV repair were described but they were associated with high early mortality and unsatisfactory late results (54) in this early era.

THE MAYO CLINIC EXPERIENCE

Danielson Repair

This repair technique was reported in 1979 and was based on the creation of a monocusp valve using the anterior leaflet.

This consisted of plication of the free wall of the atrialized RV, posterior tricuspid annuloplasty, and right reduction atrio- plasty (55).

Modified Danielson Repair

We have incorporated various modifications since then, depending on the numerous variants encountered with Ebstein's hearts (56). One of these modifications involves bringing the anterior papillary muscle(s) toward the ventricular septum, which facilitates coaptation of the leading edge of the anterior leaflet with the ventricular septum (Fig. 39.21A–C). Generally, an anteroposterior tricuspid purse-string or ringed annuloplasty is used, and atrialized right ventricular plication is performed selectively. This results in a TV repair at the level of the functional annulus, in contrast to the original repair, which brought the hinge point of the functional annulus up to the true annulus. A more recent modification includes patch augmentation of the mid-anterior leaflet with surgical delamination of attachments to the anterior and/or inferior leaflets.

In a recent review of 539 patients with Ebstein anomaly that had 604 cardiac operations, the mean age was 24 years (range, 8 days to 79 years) and 317 were female. One hundred and forty-three (26.5%) patients had a prior invasive cardiac procedure. At the time of the first operation, 182 patients had TV repair, and 337 had TV replacement. The 30-day mortality was 5.9% for the entire cohort (2.7% after 2001). Late survival was 84.7% at 10 years and 71.2% at 20 years (57).

THE BRAZIL EXPERIENCE (da SILVA APPROACH)

Recently, we have adopted the cone repair described by Dr. da Silva from Brazil when the anatomy allows, as this technique is the most anatomic of all the repair techniques described (details of cone technique are described below) (Fig. 39.22 A–J). Specifically, some septal leaflet should be present, which facilitates this repair technique. As noted above with the modified

Figure 39.18. A–D: Biventricular repair of neonatal Ebstein (Knott-Craig): A: Partition of the TV orifice into two openings by approximation of the annuloplasty stitch. B: Once the valve is judged to be competent, the “caudal” orifice is closed, thereby plicating the atrialized portion of the RV. C: Creation of a competent monocuspid valve by taking down the anterior leaflet from the annulus, fenestrating it, and augmenting it with a pericardial patch. D: The ASD is closed with a fenestrated patch, and an annuloplasty stitch is placed with one pledgetted end in the coronary sinus and the other pledgetted end at the location of the commissure between anterior and posterior leaflets. ASD, atrial septal defect. (Reprinted from Knott-Craig CJ, Goldberg SP. Management of neonatal Ebstein’s anomaly. *Semin Thorac Cardiovasc Surg Pediatr Card Surg Annu* 2007;112–116, with permission from Elsevier.)

Management of neonatal Ebstein’s anomaly. *Semin Thorac Cardiovasc Surg Pediatr Card Surg Annu* 2007;10:112–116, with permission from Elsevier.)

monocusp technique, we also have a low threshold to augment anterior leaflet size to facilitate leaflet coaptation. The cone technique represents the most anatomic repair by completion of the delamination process of the TV, providing 360 degrees of leaflet tissue around the AV junction with its hinge point at the AV groove (true annulus). Although not initially described with this technique, we do supplement the repair with a flexible anterior annuloplasty band from anteroseptal commissure to inferoseptal commissure whenever possible.

THE FRENCH EXPERIENCE (BROUSSAIS APPROACH)

In 1988, Carpentier et al. (11) proposed a repair that used mobilization of the anterior leaflet of the TV. For their types B and C, temporary detachment of the anterior leaflet and adjacent part of the posterior leaflet was followed by longitudinal plication of the atrialized ventricle and adjacent RA, repositioning of the anterior and posterior leaflets to cover the orifice area at the normal level, and remodeling and reinforcement of the tricuspid annulus with a prosthetic ring.

From 1980 to 2007, 269 patients were operated on with this technique. The mean age was 25 ± 16 years (1 to 70 years). Forty-two percent and sixteen percent were in functional class III and IV, 39% were cyanotic and 58% with permanent sinus rhythm. Ninety-eight percent underwent TV repair and 2% (five patients) had replacement. The overall hospital mortality was 9% (24 patients). Actuarial survival at 20 years was $80 \pm 5\%$. Eighty-four percent were in functional class I or II. Residual TV insufficiency (grade 3+) was present in 7%, but it was usually well tolerated when a bidirectional shunt was performed. Reoperations occurred in 9% (20 pts), two were transplanted, 12 patients had a second repair and six patients a valve replacement. Eighty-four percent remained in sinus rhythm, 5% experienced supraventricular tachycardia (usually well tolerated), and 6% had a persistent atrial fibrillation. Seven patients (5%) had an AV block and a pacemaker was implanted. It is unclear whether late problems will develop because of devitalized TV tissue related to reattachment.

THE CONE RECONSTRUCTION (da SILVA)

In 2007, da Silva et al. (58) published a series of 40 patients who had repair with the cone reconstruction (Fig. 39.22A–J). The

operative mortality was 2.5%. Mean follow-up was 4 years (range, 3 months to 12 years), only one patient died and two patients required late TV rerepair. The cone technique has the potential to cause TV stenosis, although no patient in his series had this complication. Additional follow-up is required to determine the long-term durability of this method of repair.

We consider the following as relative contraindications to the cone reconstruction technique: (a) age >50 years, (b) moderate pulmonary hypertension, (c) significant left ventricular dysfunction: ejection fraction <30%, (d) complete failure of delamination of the septal and posterior leaflets with poor delamination of the anterior leaflet (<50%), (e) severe right ventricular enlargement, and (f) severe TV annular dilatation (right AV junction)

THE VENTRICULIZATION PROCEDURE

Ullmann et al. (59) published their results with the ventricularization procedure in 2004. This is characterized by reintegration of the atrialized portion of the RV into the right ventricular cavity (ventricularization). This can be obtained by orthotopic transposition of the detached septal and posterior leaflets of the TV. The reimplanted septal leaflet serves as an opposing structure for coaptation of the reconstructed AV valve (59). Between March 1993 and April 2003, they performed this technique in 23 patients aged 13.6 (4.1 to 52.6) years. One early death (4.4%) occurred and was caused by right heart failure. Follow-up was 4.6 (0.5 to 10.9) years. Rupture of the fixation sutures occurred in three patients (13%) causing significant AV valve regurgitation, which required reintervention at 3 (0.03 to 4) months postoperatively, with rerepair of the valve in two patients and replacement in the other one (51).

OTHER REPORTED TECHNIQUES

Many others, including Hetzer et al. (60) and Quaegebeur et al. (61), have reported their repair techniques for Ebstein’s anomaly in older children and adults. Wu and Huang (62) reported a series of 34 consecutive patients who underwent removal and reattachment of the posterior and septal leaflets with or without pericardial reconstruction of the septal leaflet. There were no operative mortality and there was only mild or no TR in all patients at time of hospital dismissal. Mean

Figure 39.21. A: Basic principles of one of the modified Danielson technique for repair of the TV. The maneuvers are designed to progressively bring the leading edge of the anterior leaflet closer to the ventricular septum, or septal leaflet to optimize leaflet coaptation and establish competence of the valve. The base of the intact major papillary muscle, which arises from the free wall of the RV, is moved toward the ventricular septum at the appropriate level with pledgeted horizontal mattress sutures. **Inset:** Coronal view of the RV and RA demonstrating a small dimple effect that occurs in the anterior free wall of the RV after this maneuver is completed. **B:** The inferior angle of the tricuspid orifice is closed by bringing the right side of the anterior leaflet down to the septum and plicating the nonfunctional inferior leaflet in the process (arrow). **Inset:** After all of the mattress sutures are secured, improved proximity of the leading edge of the anterior leaflet with the ventricular septum is noted. **C:** Plication of the inferior angle of the annulus with pledgeted mattress sutures (arrow). An anterior pursestring annuloplasty (arrowhead) may be performed to further narrow the tricuspid annulus. This annuloplasty may begin at the anterosseptal commissure, anterior to the membranous septum, and end beyond the inferoseptal commissure, adjacent to the coronary sinus. Alternatively, the annuloplasty can be performed posterolaterally to reduce the size of the annulus, which also brings the free wall closer to the septum. CS, coronary sinus; AL, anterior leaflet; IL, inferior leaflet; PFO, patent foramen ovale; VS, ventricular septum; LV, left ventricle; RV, right ventricle. PV, pulmonary valve. (Copyrighted and used with permission of Mayo Foundation for Medical Education and Research.)

follow-up was 25 months (range, 1 to 55 months), with no evidence of TR in 28 patients (82%), mild regurgitation in three patients (9%), and moderate regurgitation in three (9%). Chen et al. (63) published their results of vertical plication and valve leaflet reimplantation in 2004. Twenty-five patients, with a mean age of 14 years, had TV repair. The majority of patients did well, with good functional outcomes, but 40% of them had moderate to severe TR postoperatively, and three patients required reoperation at an average follow-up of

4.1 years. Thus, TV repair techniques continue to evolve, and there is not one universally correct repair technique because of the variations in anatomy of patients with Ebstein's anomaly.

Tricuspid Valve Replacement

Every effort should be made to repair the TV rather than replacing it, but if TV repair is not feasible, then porcine bioprosthetic valve replacement remains a good alternative. We prefer

Figure 39.22 A–J: Operative steps for “da Silva technique” for Ebstein’s anomaly repair: A: The first incision is made with a no. 15 blade in the anterior leaflet at 12:00; the incision is a few millimeters away from the true annulus. The incision is then extended rightward in a clockwise fashion using a scissors. It is common for there to be a true space between the anterior leaflet and the RV in this region (i.e., normally delaminated leaflet). However, when the transition is met between the anterior and inferior (*posterior*) leaflets, it is common for there to be failure of delamination (inset) resulting in fibrous and muscular attachments between the leaflet and myocardium. The diagram demonstrates the scissors approaching the area where there is some adherence of leaflet tissue to the underlying myocardium. The dissection continues in a way that a portion of distal anterior leaflet and some inferior leaflet tissue is “surgically delaminated.” The most important aspect of this surgical delamination is to incise all fibrous and muscular attachments between the body of the leaflet and the right ventricular myocardium, but to maintain intact all fibrous and (and occasionally muscular) attachments of the leading edge of the leaflet to the underlying myocardium. Importantly, do not disrupt chordal attachments to the leading edge of any leaflet. LV, left ventricle; RA, right atrium; RV, right ventricle. (Copyrighted and used with permission of Mayo Foundation for Medical Education and Research.) B: As the anterior and surgically delaminated inferior leaflet is reflected away from the right ventricular myocardium, all fibrous and muscular attachments into the body of the underside of the leaflet are incised as shown with the scissors. It is important to keep all attachments of the leading edge of the leaflet intact; if the edge is linearly attached, then surgical fenestrations are created as depicted earlier. The dotted triangle represents the atrialized RV. (Copyrighted and used with permission of Mayo Foundation for Medical Education and Research.) C: Dissection is continued with a scissors with the goal of taking down all attachments between the septal leaflet and myocardium but preserving all attachments of the leading edge to the endocardium as described above. The dissection should proceed medially all the way to the antero-septal commissure. The leaflet tissue is typically very fragile and thin in this area. There can be marked variability in the status of the leading edge of the septal leaflet as was described for the anterior and inferior leaflets. If there is a linear attachment, then surgically created fenestrations are also made in this leaflet (not shown). (Copyrighted and used with permission of Mayo Foundation for Medical Education and Research.) D: Intraoperative photo demonstrating the mobilized anterior and inferior (*posterior*) leaflets. Natural fenestrations are shown at the junction of the anterior and inferior leaflets (arrows). (Copyrighted and used with permission of Mayo Foundation for Medical Education and Research.)

Figure 39.22. (Continued) **E:** After the anterior, inferior, and septal leaflets have been completely mobilized, the cut edge of the inferior leaflet is rotated clockwise to meet the proximal edge that has been prepared of the septal leaflet. The two are approximated with interrupted 6-0 monofilament sutures completing the cone reconstruction. This results in 360 degree of leaflet tissue that will make up the new TV orifice. (Copyrighted and used with permission of Mayo Foundation for Medical Education and Research.) **F:** After the cone reconstruction is completed, the atrialized RV is examined to determine if plication is necessary. Note the position of the RCA in the true TV annulus and keep in mind that there are acute marginal branches of the RCA that can be compromised with plication. This figure demonstrates the technique for internal plication of the atrialized RV. Monofilament 5-0 is utilized and the suture is begun distally, that is, closest to the apex of the RV. It is important to frequently examine the outside of the inferior wall of the RV to insure that inadvertent compromise of branches of the RCA is avoided. (Copyrighted and used with permission of Mayo Foundation for Medical Education and Research.) **G:** The suture line is advanced toward the base of the heart, that is, toward the AV groove. As the dotted lines of the triangle are effectively approximated, the atrialized RV is excluded. It is important for this suture line to stop approximately 1 cm before reaching the AV groove to avoid injury or distortion of the RCA. After the sides of the triangle are approximated, the entrance into the excluded atrialized segment of the RV is then closed to eliminate the “blind pouch.” (Copyrighted and used with permission of Mayo Foundation for Medical Education and Research.) **H:** After the plication or resection is completed, the newly constructed TV is then reattached at the level of the true tricuspid annulus. Because the neoTV will have an orifice that is smaller than the original dilated AV junction, a plication of the inferior annulus is necessary to meet the size of the neoTV. The inferior annulus is usually plicated with two to four simple or figure-of-eight 5-0 monofilament sutures. Proper placement of these sutures is critical to the success of this repair. The sutures need to be deep enough to maintain the integrity of the new annulus intact *without* compromising or significantly distorting the RCA. If the size discrepancy between the true tricuspid annulus and the neoTV is large, smaller annular plication sutures should be placed in multiple areas around the true annulus to avoid distortion of the RCA by a large plication in a single area. To avoid heart block, the suture line is deviated slightly cephalad to the membranous septum and AV node, which is marked by the previously mentioned vein and fatty tissue. RCA, right coronary artery. (Copyrighted and used with permission of Mayo Foundation for Medical Education and Research.)

Figure 39.22. (Continued) **I:** The completed cone reconstruction of the TV. Saline is injected via bulb syringe into the RV to examine competency of the TV. Any residual fenestrations or areas of leak are repaired as needed. A subtotal closure of the PFO or ASD is usually performed. If it is felt that a bidirectional Glenn shunt is needed because of a small effective orifice of the neoTV, or because of severely depressed RV function; then the intra-atrial communication may be closed completely. Redundant RA is excised from each side of the atriotomy and then the atriotomy is closed. RCA, right coronary artery. (Copyrighted and used with permission of Mayo Foundation for Medical Education and Research.) **J:** The completed cone reconstruction of the TV for Ebstein's anomaly. This represents an "anatomic repair" because there is 360 degrees of tricuspid leaflet tissue that surrounds the orifice of the TV and it is anchored at the level of the normal right AV junction (true TV annulus). Extreme forms of thinned, atrialized RV are plicated and redundant RA is excised. (Copyrighted and used with permission of Mayo Foundation for Medical Education and Research.)

bioprostheses to mechanical valves due to the relatively good durability (Fig. 39.23) and the lack of need for anticoagulation (64,65). However, bioprosthetic valves are less durable and are more prone to structural valve deteriorations in infants and young children than in adults with a high likelihood of reoperation (66,67). This decreased durability in young children is related to increased calcification and also to rapid somatic growth that results in patient-prosthesis mismatch. On the other hand, mechanical valves in the tricuspid position are associated with higher frequency of thromboembolic complications especially in the presence of right ventricular dysfunction (68).

To avoid the potential for RVOT obstruction during TV replacement, the anterior leaflet tissue toward the RVOT is excised. The suture line is deviated to the atrial side of the AV node and membranous septum to avoid injury to the conduction tissue (Fig. 39.24). The AV node location usually is marked by a small vein crossing the tricuspid annulus adjacent to the membranous septum. The suture line should be deviated toward the atrial side of the TV annulus anteriorly and posterolaterally where the tissues frequently are very thin to avoid injury to the vulnerable RCA. The coronary sinus, can be left to drain into the RA if there is a sufficient distance between it and the AV node; but if the distance is short, then it can be

Figure 39.23. A,B: Patients were divided into two groups (<12 years old, and ≥12 years old) and stratified into patients who had TV repair or replacement. The age cutoff was chosen because an adult-sized TV prosthesis can generally be inserted into a 12-year-old patient. In survival free from late reoperation on the TV, there was no difference between repair and replacement in adult patients (≥12 years old). However, there was a significant advantage for young patients (<12 years old) who had a TV repair versus TV replacement ($p < 0.001$). (Copyrighted and used with permission of Mayo Foundation for Medical Education and Research.)

Figure 39.24. A,B: Diagram for TV replacement technique; in Ebstein's anomaly. A: The valve suture line is placed on the atrial side of the membranous septum and AV node to avoid injury to the conduction system. The suture line is also deviated cephalad to the tricuspid annulus posterolaterally when the tissues are thin, to avoid injury to the RCA. When there is sufficient distance between the coronary sinus and the AV node, the coronary sinus may be left on the atrial side of the suture line. B: The sutures are tied with the heart perfused and beating to ensure that a conducted rhythm is preserved. (Copyrighted and used with permission of Mayo Foundation for Medical Education and Research.)

left to drain into the RV in order to avoid AV block by sutures placed too close to the conduction tissue. The struts of the porcine bioprosthesis should straddle the area of the membranous septum and conduction tissue also as an effort to avoid AV block. After septal defects are closed, tricuspid replacement can be performed on bypass without aortic clamping, which also can be helpful when there is significant ventricular dysfunction because it reduces the ischemic time. It is advisable to tie the sutures while the heart is beating, to detect any rhythm disturbance that may happen.

We prefer mild or less regurgitation after repair but accept moderate regurgitation to delay the time of valve replacement as much as we can in young children. In our experience in both pediatric and adult populations, bioprostheses in the tricuspid position have greater durability than bioprostheses in other cardiac positions, even when compared with tricuspid bioprostheses for non-Ebstein cases (57). This may be due, in part, to the large size of bioprosthesis that can be implanted relative to the patient somatic size and, the other factor may be the low right ventricular systolic pressure that is almost always present in Ebstein's anomaly. Both of these factors decrease turbulence and stress on the bioprosthesis. We avoid the use of mechanical valves in the tricuspid position in the presence of significant right ventricular dysfunction, as the discs may not open and close properly, which will increase the chance of valve thrombosis despite adequate anticoagulation. Mechanical valve replacement can be considered for adult patients who are taking warfarin anticoagulation for other indications and who want to potentially minimize the need for a subsequent reoperation for bioprosthetic deterioration provided right ventricular function is reasonable.

One and Half Ventricle Repair

The BDCPA has been used in selected patients with Ebstein's anomaly. The BDCPA does two important things in the setting of Ebstein's anomaly. First, it reduces venous return to the enlarged, dysfunctional RV by approximately one-third, and second, it provides sufficient preload to the LV to sustain adequate systemic perfusion when right-sided output is low. While some surgeons apply the BDCPA to repair of Ebstein's anomaly routinely (French reference), it has been our approach to utilize it selectively (Quinnonez and Hanley reference).

Indications for the BDCPA include: (a) severe RV enlargement and/or dysfunction, (b) a squashed LV (D-shaped LV), (c) moderate degree of TV stenosis (mean gradient >6 mm Hg) as a result of reduction in the valve orifice area after repair, and (d) RA:LA pressure ratio >1.5 , which indicates poor RV function. Other indications include preoperative cyanosis at rest or with exercise, which also indicates decreased RV function.

The BDCPA has the following disadvantages: (a) pulsations of the head and neck veins, (b) facial swelling, (c) development of pulmonary arteriovenous fistulae (69) and, (4) compromised access to the heart from the internal jugular vein approach for electrophysiologic studies or for pacemaker placement, if needed in the future.

Left ventricular dysfunction may be present in Ebstein's anomaly especially when there is a significant right ventricular dilatation or dysfunction. Whether this is due to a change in the geometry of the LV because of RV enlargement or whether it is due to an actual reduction in LV function is not known. However, it is important to document by direct pressure measurements the pulmonary arterial and left atrial pressures (LAP) before committing to a BDCPA. We prefer that the left ventricular end-diastolic pressure (LVEDP) is <12 mm Hg, the transpulmonary gradient <10 mm Hg, and the mean pulmonary arterial pressure <16 mm Hg, before considering a BDCPA. LV dysfunction can cause an increase in LVEDP, LAP, and pulmonary artery pressures. However, it often is still feasible to perform BDCPA in the presence of moderate left ventricular dysfunction (ejection function of 35% to 40%) in the setting of Ebstein's anomaly, but permissible hemodynamics should be confirmed. The BDCPA also may allow greater amounts of residual TR to be tolerated. The smaller regurgitant volume and the unloading of the RV may allow patients to tolerate longer intervals between repeat TV operations performed for failing TV prostheses or progressive valve regurgitation. Finally, if the repair has resulted in mild or moderate tricuspid stenosis (mean gradient 5 to 10 mm Hg) the gradient will be reduced by reduction in systemic venous return with the BDCPA (70). Chavaud et al. (71,72) and Quiñonez et al. (73) have proposed that the use of a bidirectional cavopulmonary shunt may decrease operative mortality and facilitate postoperative management when there is severe right ventricular dysfunction. The application of the BDCPA in patients with Ebstein's anomaly is increasing: in a

series of 150 patients in a European registry, approximately 26% underwent a 1.5-ventricle repair (74). The late results of the BDCPA approach are unknown.

We believe that the use of cavopulmonary anastomosis in Ebstein's anomaly should be reserved for selected patients until the late outcomes are well described, but it is considered a promising option especially in the presence of right heart failure.

Plication of Atrialized Right Ventricle

Plication (Fig. 39.22F and G) or resection of the atrialized portion of the RV in Ebstein's anomaly is controversial. The theoretical advantages may include: (a) decreasing the size of the nonfunctioning portion of the RV, which may speed the exit of blood from the right side of the heart, (b) minimizing the pancake effect of the RV on the LV, which may improve the left ventricular contractility and cardiac output, (c) eliminating tension on the TV repair, especially with a complex repair that incorporates multiple suture lines (e.g., cone reconstruction), and (d) allowing more space for the lung since the RV is reduced in size. The potential risk with the plication or resection process is the interruption of some coronary arterial supply to the RV, and the risk of RCA injury, both of which will predispose to ventricular arrhythmias and compromise ventricular function.

In our practice, plication of the atrialized RV is done selectively. We plicate the atrialized RV if it is thin, transparent, and dyskinetic intraoperatively. We always inspect the right coronary and posterior descending coronary arteries during the plication process to insure that it is not kinked or compromised during the course of plication.

Right Reduction Atrioplasty

There is almost always a significant right atrial dilatation in Ebstein's anomaly; so we perform right reduction atrioplasty routinely at the time of atriotomy closure. We take great care to avoid suture placement in the crista terminalis at the time of atriotomy closure in order to decrease the incidence of atrial tachyarrhythmias (75,76).

Surgical Treatment of Arrhythmias

The most common atrial tachyarrhythmias in Ebstein's anomaly are atrial fibrillation and flutter. We have used successfully the right-sided cut-and-sew lesions of Cox-maze III procedure in Ebstein's anomaly. With the availability of newer devices such as radiofrequency or cryoablation, the procedure time for maze procedure is shortened significantly. Consequently, our current preference is to perform a biatrial maze procedure, particularly when there is chronic atrial fibrillation, left atrial dilatation, or concomitant mitral regurgitation. We follow the lesions in both atria that have been previously described (77,78) (Fig. 39.25). In the presence of atrial flutter, we prefer to add a "right atrial isthmus" lesion, which is the posterolateral TV annulus to the coronary sinus to the inferior vena cava. We also make an effort to close the left atrial appendage.

In patients with AV nodal re-entrant tachycardia who underwent unsuccessful ablation in the electrophysiologic laboratory preoperatively, we perform perinodal cryoablation on cardiopulmonary bypass after opening the RA and closure of the intracardiac shunt. This involves multiple applications of the cryoprobe around and in the ostium (os) of the coronary sinus, which is then carried anteriorly toward the proximal AV node until temporary complete heart block is noted, at which time the rewarming is begun; normal AV conduction returns shortly thereafter. In case of accessory conduction pathway as in WPW syndrome, mapping and ablation is performed routinely preoperatively. Intraoperative mapping and ablation is rarely performed in the current era.

Figure 39.25. Diagram showing: location of cryoablation blocking lines for atrial flutter/fibrillation. TV, Tricuspid valve; AVN, AV node; CS, coronary sinus; SAN, sinoatrial node; SVC, superior vena cava; FO, foramen ovale; IVC, inferior vena cava. (Copyrighted and used with permission of Mayo Foundation for Medical Education and Research.)

Heart Transplantation

Heart transplantation rarely is necessary for Ebstein's anomaly. In our experience, the indication for transplantation is usually the presence of severe biventricular dysfunction (left ventricular ejection fraction <25%). On the other hand, patients with severe right ventricular dysfunction and normal or mild to moderately depressed left ventricular dysfunction are better served with a BDCPA at the time of TV repair or replacement. Other indications for transplantation include patients with significant left ventricular dilation and dysfunction and those with severe mitral regurgitation with significant left ventricular dysfunction. To determine the feasibility of transplantation versus conventional surgery, hemodynamic cardiac catheterization to ascertain left-sided filling pressures and pulmonary artery pressures is recommended.

PREGNANCY AND EBSTEIN'S ANOMALY

Pregnancy in the presence of Ebstein's anomaly always poses a challenge. Fertility is not affected, but close observation always is required by the treating obstetrician and cardiologist to optimize the best outcome. In an analysis of pregnancy outcome in four females, Chopra et al. (79) reported that pregnancy was well tolerated and there were eight vaginal deliveries with two premature ones. The mean birth weight was 2.54 ± 0.88 kg. No cardiac anomaly was found in six babies, but there was an unexplained death in one and no data was available in the other one. One patient had right heart failure during early pregnancy, and another one had an arrhythmia during labor, which was managed medically. Among the Mayo Clinic experience (80), we recorded a total of 275 pregnancies among 82 women. The incidence of congenital heart disease in children of a parent with Ebstein anomaly was 3.9%, which is significantly higher than the expected incidence of 0.75% in the general population. However, it is nearly identical to the 4% incidence in Ebstein anomaly reported by Drenthen et al. (81) and previous reports from our institution (82). In addition, it is consistent, with the incidence in children born

Figure 39.26. Freedom from any reoperation is shown with the time zero being the first operation at Mayo Clinic. (Copyrighted and used with permission of Mayo Foundation for Medical Education and Research.)

to a parent with aortic stenosis, pulmonary stenosis, or VSD (1.2% to 3.9%, CI 0.01% to 7.5%) (81)."

FUNCTIONAL OUTCOME AFTER SURGERY

Most of the literature focuses on survival and reoperation with very little discussion about the functional outcome for patients with Ebstein's anomaly after surgery. We recently reported our experience of 539 patients with Ebstein's anomaly who underwent 604 cardiac operations (80). The mean age at the initial operation was 24 years (range 8 days to 79 years) and 53% were female. Survival at 5, 10, 15, and 20 years was 94%, 90%, 86%, and 76%, respectively. Survival free of late reoperation (Fig. 39.26) was 86%, 74%, 62%, and 46% at 5, 10, 15, and 20 years, respectively. Two hundred and thirty-seven (83%) patients were in NYHA functional class I or II, and 34% were taking no cardiac medication. The reported exercise tolerance was comparable to that of the patients' peers. In a small subset of these patients, formal exercise testing

was conducted (83,84). There was improvement in exercise tolerance (Fig. 39.27) after operation, but this improvement was believed to be a result of the elimination of the right-to-left shunt at the atrial level rather than improvement in ventricular function. Late reoperation, rehospitalization, and atrial tachyarrhythmias continue to be a problem, with a rate of freedom from rehospitalization (for cardiac causes including reoperation) of 91%, 79%, 68%, 53%, and 35% at 1, 5, 10, 15, and 20 years, respectively (72). Thus, further improvements in the durability of TV repair and replacement, as well as improved control of atrial arrhythmias, may lead to improved quality of life in patients with Ebstein's anomaly.

CONGENITAL NON-EBSTEIN TRICUSPID VALVE REGURGITATION

Congenital TV regurgitation is a relatively uncommon condition that includes a heterogeneous group of lesions with a unique management strategy. There are wide anatomical variations that lead to TR in patients without Ebstein malformation. Possible etiologies may include primary valve abnormalities, for example, congenital absence of chordae (85) or TV dysplasia in congenitally unguarded TV orifice (86), and patients with pulmonary atresia and intact ventricular septum (87), which can be similar to the valves of Ebstein's anomaly, or secondary regurgitation in association with other anomalies as in atrio VSDs (88), cc-TGA (24), congenital coronary arterial fistula with secondary right ventricular enlargement (89), and Uhl's anomaly (90). Iatrogenic causes in infants, children, and adolescents include TR secondary to previous VSD closure (chordal or leaflet injury), pacemaker or internal cardioverter-defibrillator lead-induced TR (91), and traumatic TR (ruptured chordae) (92). The presentations depend on the severity of the disease and it may be apparent in infancy, childhood, or adulthood (93).

In general, there are two categories of TV dysplasia—those with and those without downward displacement. Cases with downward displacement, which is due to failure of delamination of valve leaflets from underlying myocardium, are by definition, Ebstein malformation. Although downward displacement often is given as the sole feature of Ebstein malformation, dysplasia of the leaflets and subvalvar apparatus are

Figure 39.27. Self-reported activity scale after operation for Ebstein anomaly is shown with the percentage of survey responders who rated their exercise tolerance related to other people their own age on a scale of 1 to 10. (Copyrighted and used with permission of Mayo Foundation for Medical Education and Research.)

an almost universal feature as well. The pathognomic findings of Ebstein malformation are downward displacement, whether or not features of dysplasia are present, and a myopathy of the RV as a result of failure of delamination. When downward displacement is absent, then the anatomic entity is referred to as “tricuspid valvular dysplasia (94).”

Echocardiography confirms the diagnosis, determines the degree of TR, allows accurate evaluation of the tricuspid leaflets and subvalvar apparatus (displacement, tethering, dysplasia, etc.), size and function of the RV and LV, and detection of an ASD.

Magnetic resonance imaging (MRI) is being used increasingly in all types of patients with cardiac disease, including those with Ebstein's anomaly and other forms of congenital TR. Functional assessment can be made including quantitative measurements of left and right ventricular size and function. At the present time, we utilize echocardiography (2- and 3-D) for evaluation of TV anatomy and MRI for assessment of right ventricular size and function.

TR has been considered a benign lesion for a long time, but recent studies suggest that irrespective of pulmonary artery pressure or left ventricular ejection fraction, TR negatively affects long-term survival (95). The reported 2-year postoperative event-free survival in the presence of severe preoperative right ventricular dysfunction is 57% (96). Severe TR induces chronic right ventricular volume overload, which leads to progressive ventricular dilatation, dysfunction, and eventually right-sided heart failure. Timely correction of TR will preserve right ventricular function, improve functional capacity, and improve long-term survival. TV repair is the preferred treatment strategy when it is feasible, particularly in children. Optimal timing is now recommended before the onset of right ventricular dysfunction even in asymptomatic patients (97,98). The surgical indications in TR are not clearly identified, but generally include symptoms or cyanosis (when ASD is present), decreased exercise tolerance, progressive cardiomegaly on chest x-ray, progressive right ventricular dilatation or reduction of right ventricular systolic function by echocardiography, or appearance of atrial or ventricular arrhythmias. In borderline situations, the echocardiographic determination of high probability of TV repair makes the decision to proceed earlier with operation easier. This may be explained by the following: few data exist on postoperative outcomes; and the overall prevalence of TR as compared with left-sided valvular disease is low.

The goal of operation is repair of the TV whenever possible. In order to increase the number of successful TV repairs, particularly in children, we have been utilizing a cone-type reconstruction (58,99), which results in 360 degrees of tricuspid leaflet tissue surrounding the right AV junction. This allows leaflet tissue to coapt with leaflet tissue, similar to what occurs with normal TV anatomy. The hinge point of the reconstructed TV is at the true TV annulus (AV junction). Alternatively, a monocusp-type repair based on a large anterior leaflet has also been successful (57,64). It is important that the repair is tension free. In order to facilitate this, augmentation of the mid-anterior leaflet with an ellipse of autologous pericardium or other pliable synthetic material can increase the height of the anterior leaflet, which facilitates coaptation with the ventricular septum while minimizing tension at an inferior annuloplasty line. Importantly, we avoid the creation of complete pericardial leaflets (from annulus to leading edge) because of poor durability. We use *flexible* annuloplasty C-shaped rings (from anteroseptal commissure to inferoseptal commissure) liberally since significant tricuspid annular dilation is often present and the possibility of iatrogenic tricuspid stenosis is low. Finally, closure of intra-atrial shunts and right reduction atriotomy are routine, and the maze procedure is performed when atrial tachyarrhythmias are present.

Prosthetic TV replacement remains a good alternative for the treatment of TR when valve repair is not feasible. Porcine bioprosthetic valve replacement, as opposed to mechanical valve replacement, is generally preferred because of relative good durability of the porcine bioprosthesis in the tricuspid position and the lack of need for chronic warfarin anticoagulation. Mechanical TV replacement should be advised in selected circumstances since there is a higher frequency of prosthetic valve dysfunction (thrombosis) compared to mechanical valves in other cardiac positions, particularly when right ventricular function is poor. In general, postoperative management includes short term (3 months) warfarin anticoagulation for porcine bioprostheses and life long aspirin, 81 mg daily. When a mechanical valve is used, the target international normalized ratio (INR) is 3 to 3.5 in addition to aspirin, 81 mg daily.

The wide and infinite variability of anatomic abnormality with Ebstein malformation and congenital TV dysplasia demonstrate that every valve is a little different and no two hearts are alike...illustrating why this lesion continues to be one the most challenging valve lesions for the surgeon. There have been more reports in the literature of tricuspid valvuloplasty techniques for Ebstein malformation and congenital tricuspid dysplasia than any other valve lesion in the cardiac arena. While the ability to obtain a competent, durable tricuspid repair has improved in recent years, the surgical treatment of the congenitally abnormal TV is still considered palliative since the many patients will require more than one operation in their lifetime.

UHL'S ANOMALY

History

William Osler in 1905 described the term “parchment heart,” but Henry Uhl reported the first case in 1952 (100).

Pathology

In Uhl's anomaly, there is complete or partial absence of the myocardial layer of the RV and the endocardium and the epicardium become opposed, but the septal component, septomarginal trabeculation, and the papillary muscles of the TV are normally muscularized (101). The absence of myocardium may be the result of primary nondevelopment of myocytes or a form of selective apoptosis. Most cases are sporadic and Feucht et al. (102) suggested the role of vascular endothelial growth factor in the induction of this cardiovascular malformation.

Prevalence

Uhl's anomaly is extremely rare. Gerlis et al. (103) in 1993 reported only 84 cases since the beginning of the 20th century. It is mainly sporadic although some familial occurrences have been reported.

Clinical Presentation

Congestive heart failure with associated peripheral edema and pleural effusion is the most frequent symptom. Arrhythmias and conduction disturbances are not common in Uhl's anomaly as in arrhythmogenic right ventricular dysplasia due to the absence of foci that transmit abnormal electrical activity (103).

Associated Anomalies

Pulmonary atresia with intact ventricular septum

Differential Diagnosis

- Ebstein's anomaly
- Arrhythmogenic right ventricular dysplasia:

In arrhythmogenic right ventricular dysplasia, there is a patchy replacement of the right ventricular muscle with fibrofatty tissue. Arrhythmia, palpitations, syncope, or sudden death are common presentations.

Treatment

Treatment includes medical management of congestive heart failure, and drainage of pleural effusions. Surgical options include:

- Right ventricular exclusion (104): with atrial septectomy, BDCPA, and closure of the TV orifice.
- One-and-half ventricle repair (105): with BDCPA and partial right ventriculectomy and atrial septectomy.
- Cardiac transplantation (106).

Lourdes R. Prieto ■ Larry A. Latson

Congenital obstruction to right ventricular outflow is most commonly due to pulmonary valve stenosis, but may also be intracavitary or supra-valvar and involve the main and branch pulmonary arteries. Pulmonary stenosis at some level, with and without other associated lesions, occurs in 25% to 30% of all patients with congenital heart disease. This chapter discusses all levels of pulmonary stenosis with intact ventricular septum.

ISOLATED VALVAR PULMONARY STENOSIS

Isolated pulmonary valve stenosis is found in 80% to 90% of all patients with right ventricular outflow obstruction. It was described in 1761 by John Baptist Morgagni (1) and initially was thought to be rare. With improved diagnostic capability, however, pulmonary valve stenosis has been found in 8% to 10% of patients with congenital heart disease.

Familial occurrence of pulmonary stenosis has been reported. Campbell (2) found a 2.1% incidence of cardiac disease, usually pulmonary stenosis or tetralogy of Fallot, in siblings of patients with pulmonary stenosis. In the Second Natural History Study of Congenital Heart Defects, the occurrence of definite and possible congenital cardiac defects in 1,356 siblings of 449 patients with valvar pulmonary stenosis was 1.1% and 2.1%, respectively (3).

Embryology and Pathology

The process of cardiac valve development begins with migration of a subset of endothelial cells lining the inner layer of the developing heart tube into the extracellular matrix that separates the inner endothelial layer from the outer layer of myocardium, forming cardiac cushions precisely in the areas overlying the future atrioventricular canal and outflow tract. The cells forming these cushions continue to proliferate and differentiate into mesenchymal cells. Whereas the mitral and tricuspid valves are derived only from endocardial cushion tissue, the final development of the aortic and pulmonary valves involves migration of neural crest cells from the branchial arches to the distal outflow tract where aortopulmonary septation will take place (4,5). Further remodeling of these cushions culminate in the formation of thin, tapered leaflets with a single endothelial cell layer and a central matrix of collagen, elastin, and glycosaminoglycans.

Normal valve development involves several signaling pathways that tightly regulate endothelial cell differentiation and remodeling, and is also dependent on the interaction between these endothelial cells, the extracellular matrix, and the surrounding myocardium (6). The complex interaction between

these pathways can be disrupted at various levels, resulting in a malformed valve. For example, deletion of CXCR7, a G-protein-coupled receptor found in cushion mesenchymal cells in the developing heart, resulted in aortic and pulmonary valve stenosis in mouse embryos due to excessive proliferation of mesenchymal valve cells associated with increased bone morphogenetic protein signaling (7). Deletion of Ptpn11 exon 2, which encodes the protein tyrosine phosphatase SHP-2 involved in another signaling pathway, results in dysplastic outflow valves (8). Notably, PTPN11 mutations are found in patients with Noonan syndrome and LEOPARD syndrome, both manifesting pulmonary valve stenosis (9–11). Research to date has elucidated disruptions that affect the development of both the pulmonary and aortic valves, but factors resulting specifically in pulmonary valve abnormalities have yet to be recognized. The pathways controlling the later stages of valve remodeling that would affect one or the other semilunar valve are not yet known.

In the classic form of pulmonary valve stenosis, the valve is conical or dome shaped, and two to four raphe may be visible, but there is no separation into valve leaflets (12) (Fig. 40.1). Less commonly, the valve may be diffusely thickened with one, two, or three leaflets and commissural fusion. A distinct pathology termed pulmonary valve dysplasia has been described in 10% to 20% of patients (13). Dysplastic valves are trileaflet with markedly thickened cusps composed of disorganized myxomatous tissue and little, if any, fusion (Fig. 40.2). The valve annulus is usually hypoplastic. This entity is found in most patients with Noonan syndrome and may be seen in nonfamilial cases.

Secondary changes in the right ventricle (RV) and pulmonary arteries can occur as a result of pulmonary valve obstruction. The RV, particularly the infundibular region, becomes diffusely hypertrophied. Hypertrophy of the infundibulum can produce dynamic subvalvar obstruction (Fig. 40.1). At autopsy, small myocardial infarctions frequently have been seen in the subendocardium of the right ventricular free wall and papillary muscles in patients with severe pulmonary stenosis. Thickening of the tricuspid valve and chordal attachments may be present, and the valve may become regurgitant. The right atrium may be thick and dilated as a result of the increased pressure necessary to fill the hypertrophic RV. In many cases, a patent foramen ovale or, less often, an atrial septal defect is seen.

Most patients develop poststenotic dilation of the pulmonary artery trunk, sometimes extending to the proximal left pulmonary artery (LPA). One notable exception to this finding is in patients with dysplastic pulmonary valves. The degree of dilation is not necessarily proportional to the severity of obstruction, often being more pronounced in mild cases. Poststenotic dilation may result from the high-velocity jet of flow ejected through the small valve orifice.

Figure 40.1. A schematic illustration of pulmonary valve stenosis with intact ventricular septum. A: Valvular stenosis with “doming” of the pulmonary valve. B: The secondary infundibular hypertrophy can be seen. LV, left ventricle; PA, pulmonary artery; RV, right ventricle.

Physiology

The main physiologic effect of valvar pulmonary stenosis is a rise in right ventricular pressure proportional to the severity of obstruction. This elevation of right ventricular pressure is accompanied by an increase in muscle mass that occurs by one of two mechanisms, depending on the stage of development. Work in animal models has shown that the fetal and neonatal myocardium responds to increased afterload by hyperplasia of the muscle cells with a concomitant increase in

Figure 40.2. Right ventricular angiogram of a child with dysplastic pulmonary valve stenosis. The view is anteroposterior with cranial angulation. Note the thickened, irregular leaflets and relatively small annulus. Supravalvar narrowing is present, and the main pulmonary artery is not dilated.

the number of capillaries (14). In contrast, the adult myocardium responds with hypertrophy of the existing fibers, with no change in the capillary network. Thus, the neonatal myocardium may be better adapted to generate the high pressures necessary to overcome severe obstruction. Increased muscle mass may enable the hypertensive RV to maintain a normal stroke volume. If the size of the stenotic orifice remains fixed, however, the degree of obstruction becomes relatively more severe as the patient grows. The RV eventually may dilate and fail. This process is exacerbated by the development of tricuspid insufficiency in many patients with severe pulmonary stenosis. Right ventricular failure may occur in infancy if severe neonatal obstruction is present. As right ventricular output decreases with a failing ventricle, adequate tissue oxygenation can be maintained only by increasing tissue oxygen extraction. Any increase in oxygen demand, such as during exercise, may result in frank peripheral cyanosis. In patients with a patent foramen ovale or atrial septal defect, central cyanosis is observed as a result of right-to-left atrial shunting when the right atrial pressure exceeds the left atrial pressure. Progressive hypertrophy and decreased compliance of the RV, or myocardial failure with subsequent dilation, may lead to central cyanosis in some initially well-compensated patients.

When the degree of valvar pulmonary stenosis is severe enough to cause a decrease in fetal right ventricular output, a larger-than-normal atrial right-to-left shunt is established in utero. This condition has been termed critical pulmonary stenosis (15). The RV is often hypoplastic because of severe hypertrophy and the effects of reduced flow through the RV during development (Fig. 40.3). At birth, affected infants are cyanotic and have systemic or suprasystemic right ventricular pressure. Even if the stenosis is relieved, right-to-left atrial shunting and cyanosis often persist for months after the stenosis is relieved, until there is a decrease in the right ventricular hypertrophy and an increase in right ventricular size.

Manifestations

Clinical Features

Most patients with valvar pulmonary stenosis are asymptomatic, and the diagnosis usually is made when a pathologic murmur is detected on routine examination. Symptoms are rarely present in childhood but become more common with increasing age in patients with moderate to severe stenosis. Initial symptoms usually consist of exertional dyspnea and fatigue due to inability of the RV to increase its output in response to exertion. If the stenosis is not relieved, right heart failure may ensue. Cyanosis may be observed in patients with an atrial communication. Occasionally, patients with moderate to severe stenosis may experience chest pain, syncope, and even sudden death with strenuous exercise. Decreased myocardial perfusion caused by inadequate cardiac output during exercise, leading to ischemia and ventricular arrhythmias, is thought to be the mechanism for these events.

Children with valvar pulmonary stenosis usually exhibit normal growth and development regardless of the severity of obstruction. Squatting is extremely rare even in patients with significant central cyanosis. If squatting is present, other diagnoses, especially tetralogy of Fallot, should be sought.

Infants with critical pulmonary stenosis are cyanotic at birth, and the cyanosis may be severe enough to be life threatening (15). Although the right ventricular cavity is often relatively hypoplastic, the atrial communication is usually large enough to maintain cardiac output and prevent right heart failure at the expense of cyanosis. Symptoms

Figure 40.3. Right ventricular angiogram of a 1-day-old infant with critical pulmonary valve stenosis and intact ventricular septum. Right ventricular pressure was suprasystemic. **A:** The anterior view with cranial angulation shows a hypoplastic RV and a small, regurgitant tricuspid valve. **B:** The same findings are demonstrated in the corresponding lateral view. The pulmonary valve annulus is mildly hypoplastic, and the leaflets are thickened and “domed.” A thin jet of flow directed anteriorly is seen, and the main pulmonary artery is dilated.

of right-sided heart failure may be seen in some newborns with significant tricuspid insufficiency or may develop in untreated infants if the atrial communication becomes inadequate with growth.

The auscultatory findings in valvar pulmonary stenosis are quite distinctive, often allowing the diagnosis to be made based only on the physical examination (16) (Fig. 40.4). The first heart sound is normal, and in patients with mild or moderate stenosis, it is followed by a pulmonary ejection click. The click corresponds to the time when the doming pulmonary valve reaches its open position. The more severe the stenosis, the earlier in systole the click occurs, until it merges with the first heart sound and becomes inaudible. The intensity of the click varies with respiration, decreasing during inspiration and increasing during expiration.

The systolic murmur of valvar pulmonary stenosis is ejection in quality and maximal at the upper left sternal border. It may radiate over the entire precordium and neck, but characteristically is heard in the back. In general, the intensity of the murmur increases with the severity of obstruction. Mild stenosis is associated with murmurs of grade 3 or lower, and moderate to severe stenosis with grade 4 or louder. Patients with severe stenosis and right heart failure may have an unusually soft murmur because of low cardiac output. The length of the murmur is proportionately related to the duration of right ventricular ejection, which is determined primarily by the severity of obstruction. With more severe obstruction, the murmur peaks later in systole. In mild stenosis, the murmur is relatively short and peaks at or before midsystole (Fig. 40.4). In moderate stenosis, the murmur ends at or slightly after the aortic component of the second heart sound, which remains audible. With severe obstruction, the murmur extends beyond the aortic closure sound, which may become inaudible. A soft, early diastolic murmur of mild pulmonary insufficiency is rarely heard and usually results from progressive pulmonary trunk dilation.

Patients with mild pulmonary valve stenosis have normal “a” waves and therefore normal jugular venous pulsations.

Figure 40.4. Schematic illustration of phonocardiograms in mild to severe valvular pulmonary stenosis. S1, first heart sound; E, ejection sound; SM, systolic murmur; A2, aortic component of the second heart sound; P2, pulmonic component of the second heart sound; S4, fourth heart sound. (Modified from Vogelpoel L, Schrire L. Auscultatory and phonocardiographic assessment of pulmonary stenosis with intact ventricular septum. *Circulation* 1960;22:55; Perloff JK. Congenital pulmonic stenosis. In: *The Clinical Recognition of Congenital Heart Disease*. 4th ed. Philadelphia, PA: WB Saunders, 1994:209.)

With more severe obstruction, the “a” wave becomes progressively larger, and abnormal pulsations may be felt both in the jugular venous pulse and in the liver. In infants and children, jugular venous pulsations are often difficult to appreciate, even in the presence of large “a” waves.

A prominent right ventricular systolic impulse and a systolic thrill almost always can be palpated in patients with severe pulmonary stenosis. Typically, the thrill is located at the second to third intercostal space, but it may also be felt at the suprasternal notch. The thrill may be absent in young infants with severe stenosis and in patients with congestive heart failure and low cardiac output. When the stenosis is mild, the precordium is quiet and a thrill is not present.

The second heart sound in pulmonary stenosis is usually split, and the degree of splitting is proportional to the degree of stenosis. The split may become fixed in severe stenosis as a result of a fixed stroke volume. The intensity of the pulmonary component of the second heart sound typically decreases with increasing obstruction, which may make the splitting difficult to appreciate. Occasionally, in mild stenosis, the pulmonary closure sound is louder than normal because of marked dilation of the pulmonary artery trunk. A fourth heart sound often is heard at the lower left sternal border in patients with severe stenosis. When a third heart sound is heard, the presence of an atrial septal defect should be suspected.

The cardiac examination in infants with critical pulmonary stenosis may differ from that of older patients with severe obstruction. The systolic murmur of pulmonary stenosis may be deceptively soft as a result of decreased flow across the pulmonary valve in the presence of an atrial right-to-left shunt. A holosystolic murmur of tricuspid insufficiency may be present lower along the left sternal border, or a patent ductus murmur may be audible along the mid to upper sternal border. Either of these may be the predominant murmur. The pulmonary closure sound is typically absent. Significant cardiomegaly may be detected by precordial palpation, most commonly due to right atrial enlargement.

Electrocardiographic Features

The electrocardiogram can be somewhat useful in assessing the severity of obstruction in patients with pulmonary valve stenosis. As many as 40% to 50% of patients with mild stenosis have a normal electrocardiogram. Slight rightward deviation of the QRS frontal axis is often the only abnormality. The R-wave amplitude in the right precordial leads rarely exceeds 10 to 15 mm. A right ventricular conduction delay is commonly present.

In moderate pulmonary stenosis, the electrocardiogram is almost always abnormal, with only 10% of patients having a normal tracing. Right axis deviation is usually present. The R:S ratio in V1 is usually >4:1, and the R wave is typically <20 mm. The T waves in the right precordial leads are upright in approximately 50% of patients.

In severe pulmonary stenosis, the electrocardiogram is rarely normal (Fig. 40.5). The mean frontal QRS axis is usually >110 degrees, and not uncommonly, extreme right axis deviation is seen. A pure R, RS, or QR is the usual pattern in the right precordial leads, and the R wave is usually >20 mm. The R:S ratio in V6 may be <1.0. The T waves may be upright or inverted in the right precordial leads, and the P waves are abnormally tall and peaked in lead 2 and in the right precordial leads, indicating right atrial enlargement.

It is possible to estimate the right ventricular pressure in patients between 2 and 20 years of age if a pure R wave is present in lead V4R or V1. The height of the R wave in millimeters, multiplied by 5, approximates the right ventricular systolic pressure in millimeters of mercury (14). Occasionally, infants with severe stenosis, in whom the RV may be

Figure 40.5. Electrocardiogram of a child with severe valvular pulmonary stenosis. Note the qR complex and inverted T in V4R.

hypoplastic, have a more leftward axis than expected (in the range of +30 to +70 degrees) as well as evidence of left ventricular hypertrophy. A superior axis, sometimes accompanied by a conduction abnormality of the left bundle, also has been described in some patients with pulmonary stenosis. There may be a correlation between these findings and Noonan syndrome, with its associated cardiomyopathy.

Radiographic Features

The most distinctive feature in valvular pulmonary stenosis is a prominent main pulmonary artery segment resulting from poststenotic dilation of the pulmonary trunk and sometimes the LPA (Fig. 40.6). This finding is present in 80% to 90% of cases, but it may be absent in infants, in patients with dysplastic pulmonary valve, and in cases of rubella syndrome. The apex of the heart is usually rounded and points downward. The right atrial segment may be prominent, more commonly in patients with associated tricuspid insufficiency or atrial septal defect. A left aortic arch is virtually always present.

Heart size and pulmonary vascularity are usually normal in patients with mild to moderate stenosis. In the absence of right ventricular failure, even with severe obstruction, only mild cardiomegaly is seen. When heart failure develops, marked cardiomegaly results due to right atrial and right ventricular enlargement, and pulmonary vascularity is decreased as a result of a reduction in pulmonary flow. Cardiomegaly is commonly present in infants with severe or critical pulmonary stenosis, and pulmonary vascularity is severely reduced because of the large atrial right-to-left shunt (Fig. 40.7).

Two-Dimensional Echocardiography

The 2-D echocardiogram clearly demonstrates the typical features of the stenotic pulmonary valve from the standard and high parasternal short-axis and long-axis views as well as the subcostal sagittal views (Fig. 40.8). The valve leaflets usually appear prominent because of thickening. Systolic motion is restricted, with inward curving of the tips of the leaflets, known as doming. Associated features, such as poststenotic dilation of the main and branch pulmonary arteries, also are easily recognized. Right ventricular hypertrophy, contractility of the RV, as well as anatomy and function of the tricuspid valve should be assessed. Evidence of dynamic subpulmonary stenosis should be sought, but the severity may be impossible to estimate in the presence of more than mild valvular stenosis.

Figure 40.6. Roentgenogram of a boy with severe valvar pulmonary stenosis and suprasystemic right ventricular pressure. **A:** Anteroposterior view. Note the prominent right cardiac border and rounded apex pointing downward. The main pulmonary artery segment is dilated. Pulmonary vascularity is normal. **B:** The lateral view demonstrates prominence of the RV with increased filling of the space between the thoracic wall and anterior border of the heart.

The diagnosis of dysplastic pulmonary valve usually can be ascertained by echocardiography. The leaflets appear thickened and immobile, without the characteristic doming seen in typical cases. The pulmonary valve annulus is hypoplastic, and supraannular narrowing of the proximal main pulmonary artery is often present. The poststenotic pulmonary artery dilation seen in classic cases is absent.

Figure 40.7. Roentgenogram of a 1-day-old infant with critical pulmonary stenosis and congestive heart failure. The heart is markedly enlarged. The right heart border is due to severe right atrial enlargement. The pulmonary vascularity is diminished as a result of right-to-left shunting at the atrial level.

Doppler Evaluation

The Doppler echocardiogram allows quantitative assessment of severity of pulmonary valve stenosis by estimating the pressure drop across the pulmonary valve (Fig. 40.9). The simplified Bernoulli equation $P = 4V^2$ is used, where P is the peak instantaneous pressure gradient (mm Hg), across the obstructed pulmonary valve, and V is the peak flow velocity (m/s), distal to the obstructive orifice. If significant subpulmonary stenosis coexists, V_1 (the peak flow velocity proximal to the obstruction) must be taken into account. The Doppler beam must be aligned parallel with the main pulmonary artery trunk or the direction of the flow jet as seen on color Doppler. If tricuspid insufficiency is present, the Doppler technique can be used to calculate the pressure difference (P) between the right atrium and RV by measuring the peak flow velocity (V) of the tricuspid insufficiency jet. Right ventricular pressure then can be estimated by adding the pressure gradient to the estimated right atrial pressure.

Several studies have documented excellent correlation between the Doppler-derived gradient and that obtained by direct pressure measurement at catheterization (17,18). It should be recognized, however, that the Doppler-derived peak instantaneous pressure gradient exceeds the peak-to-peak pressure gradient measured at catheterization by a small amount. In pulmonary valve stenosis, this difference is clinically insignificant, and the two measurements are close enough to obviate the need for diagnostic catheterization in most patients until intervention becomes necessary.

The development of color Doppler 2-D echocardiography has contributed to the diagnostic accuracy of pulmonary valve stenosis by demonstrating an abnormal flow pattern originating at the stenotic valve (Fig. 40.8). Normal flow is coded as red or blue, depending on whether it is directed toward or away from the transducer, respectively. High-velocity, turbulent flow through stenotic lesions appears as a mosaic jet with green, yellow, and other shades. Visualization of the jet by

Figure 40.8. A: Parasternal short-axis view from a 1-day-old infant with critical pulmonary valve (PV) stenosis (same patient as in Fig. 40.3). Note the thickened, “doming” leaflets in systole. The PV annulus is hypoplastic compared with the aortic valve annulus. There is poststenotic dilation of the main pulmonary artery (MPA). color also facilitates optimization of the alignment between the Doppler sample volume and the direction of flow, increasing the accuracy of the measured gradient.

Cardiac Catheterization

The refinement of 2-D and Doppler echocardiography over the past three decades has had a dramatic impact on the use of cardiac catheterization in the management of pulmonary valve stenosis. Because diagnosis and exclusion of other significant lesions can now be accomplished noninvasively, the role of catheterization has become largely therapeutic. Balloon pulmonary valvuloplasty has supplanted surgical valvotomy as the treatment of choice for this lesion (19).

Hemodynamics

The most important measurements made at catheterization are the right ventricular pressure compared with systemic arterial pressure and the pressure gradient across the pulmonary valve. A resting right ventricular pressure >30 to 35 mm Hg and a pressure gradient across the pulmonary valve of >10 mm Hg are considered abnormal. An end-hole catheter is used to obtain carefully the withdrawal pressure recordings from the pulmonary artery to the body of the RV to assess the severity and location of any stenoses. In the presence of associated infundibular obstruction, pressure gradients are encountered across the pulmonary valve and also across the infundibulum. In the infundibular chamber, the pressure curve is usually

Figure 40.9. Continuous-wave Doppler recording from the parasternal short-axis view of a patient with severe pulmonary valve stenosis. The high-velocity systolic flow with a negative deflection from the baseline results from a jet directed away from the transducer from the RV to the main pulmonary artery. The peak velocity of the jet is 5.2 m/s, equivalent to a peak pressure gradient of 110 mm Hg across the pulmonary valve.

Figure 40.10. Right ventricular angiogram of a 17-year-old girl with severe pulmonary valve stenosis (RV pressure 122/16 mm Hg). A: Anteroposterior view with cranial angulation shows a thickened, “domed” pulmonary valve and poststenotic dilation of the main pulmonary artery. B: Lateral projection with similar findings.

triangularly shaped, with a fall in the late systolic pressure resulting from progressive narrowing of the outflow tract during ventricular contraction (20). The right ventricular end diastolic pressure may be normal, but usually it is elevated with severe obstruction or right ventricular failure. The right atrial pressure is normal in mild to moderate obstruction, but tall right atrial “a” waves usually are seen with severe obstruction. Pulmonary artery pressure is normal in mild cases, but it is decreased and dampened in severe cases. This depression of pulmonary artery pressure is more marked in the main pulmonary artery just beyond the valve than further distally because of the Bernoulli effect. The increase in flow velocity across the stenotic valve causes more of the total energy to be expressed as kinetic energy, necessitating a drop in pressure to maintain the total energy constant. As blood velocity decreases further downstream, pressure recovery is observed.

In patients with relatively normal cardiac output, classification of severity of pulmonary stenosis is routinely based on measurements of right ventricular pressure and valve gradient. Mild stenosis is characterized by a right ventricular pressure less than half the left ventricular pressure or a valve gradient <35 to 40 mm Hg. In moderate stenosis, the right ventricular pressure is greater than half but <75% of the left ventricular pressure, or the gradient is 40 to 60 mm Hg. Severe stenosis is defined as a right ventricular pressure $\geq 75\%$ of the left ventricular pressure or a gradient >60 to 70 mm Hg.

During exercise, an increase in the pressure gradient across the stenotic valve occurs primarily because an increase in the volume of flow and the rate of contraction of the RV leads to an increase in flow velocity across the obstruction. Patients with severe stenosis are unable to increase their stroke volume and rely solely on an increase in heart rate to augment cardiac output during exercise. A marked increase in heart rate can be detrimental in patients with severe obstruction because of the resultant shortening of diastolic filling time. The impedance to filling of the hypertrophied, stiff RV can

lead to a decrease in cardiac output and systolic blood pressure when marked tachycardia develops. Decreased right ventricular compliance is further evidenced by elevated right ventricular end diastolic pressure at rest and abnormal increase with exercise observed in patients with severe obstruction (21).

Angiocardiography

Angiocardiography provides information about the location and severity of pulmonary stenosis that is invaluable for diagnostic and therapeutic purposes. The anatomy of the pulmonary valve and associated features can be shown best by right ventricular angiography in the anteroposterior view with the tube angled cephalad and in the lateral view (Fig. 40.10, Video 40.1). Characteristically, the pulmonary valve leaflets are mildly thickened and dome in systole, returning to the normal position in diastole. A narrow jet of contrast is seen crossing the valve, usually along the anterosuperior margin of the main pulmonary artery, resulting in poststenotic dilation of this vessel. The pulmonary valve annulus is typically of normal size, but it may be hypoplastic in infants with severe stenosis. The right ventricular cavity is usually of normal size, but it may be hypoplastic in newborns with critical pulmonary stenosis, or it may be dilated in the presence of congestive heart failure. The walls usually are thickened with prominent trabeculations. Narrowing of the right ventricular outflow tract (RVOT) as a result of infundibular hypertrophy is usually seen in severe obstruction. Right ventricular function is normal except in severe cases with ventricular failure.

The angiographic features of dysplastic pulmonary valve stenosis differ in several ways from those of typical pulmonary valve stenosis (Fig. 40.2, Video 40.2). The valve leaflets are markedly thickened and relatively immobile, with little excursion during the cardiac cycle. The annulus is hypoplastic, and this hypoplasia usually extends to the

proximal main pulmonary artery. There is often the appearance of tethering of the valve leaflets to the main pulmonary artery wall at the sinotubular junction. Poststenotic dilation of the main or branch pulmonary arteries usually is not seen. Often the origin of the right pulmonary artery (RPA) from the main pulmonary artery has a more proximal than normal position.

Differential Diagnosis

The diagnosis of pulmonary valve stenosis with intact ventricular septum is usually readily made by careful auscultation and supportive electrocardiographic and radiographic features, but certain conditions must be considered in the differential diagnosis. Mild pulmonary stenosis should be differentiated from idiopathic dilation of the main pulmonary artery, atrial septal defect, peripheral pulmonary arterial stenosis, mitral valve prolapse, straight back syndrome, mild aortic stenosis, and innocent murmurs. Moderate to severe pulmonary stenosis without cyanosis should be distinguished from ventricular septal defect (VSD) with or without associated pulmonary stenosis and moderate aortic stenosis. When cyanosis is present in severe stenosis, tetralogy of Fallot and pulmonary atresia with intact ventricular septum must be excluded. Ebstein anomaly of the tricuspid valve occasionally mimics severe pulmonary stenosis in the newborn.

PULMONARY STENOSIS ASSOCIATED WITH SYSTEMIC DISEASES

Congenital heart disease is seen in approximately 50% of patients with Noonan syndrome (10). The most common lesion is pulmonary stenosis due to pulmonary valve dysplasia. Hypertrophic cardiomyopathy of the left ventricle with or without pulmonary stenosis is also found in up to 25% of cases. The cardiac examination in these patients is often atypical and does not reflect the severity of the pulmonary stenosis. The ejection click is usually absent, and a soft, relatively short murmur may be heard despite severe stenosis. The electrocardiogram usually shows superior axis deviation even in patients without apparent cardiomyopathy.

Intracardiac tumors or extrinsic lesions compressing cardiac structures are rare causes of pulmonary stenosis. Echocardiography or magnetic resonance imaging (MRI) usually can establish the diagnosis. Multiple lentiginos syndrome, or LEOPARD syndrome, has been associated with pulmonary or pulmonary artery stenosis. Neurofibromatosis rarely causes right ventricular outflow obstruction, as can deposits from glycogen storage diseases and gout. Carcinoid disease of the bowel may be associated with endocardial fibroelastosis of the RV with involvement of the pulmonary and tricuspid valves, leading to stenosis.

Treatment

Balloon Valvuloplasty

The technique of percutaneous balloon pulmonary valvuloplasty was described initially by Kan et al. (19). Since then, many other workers have reported the successful application of this technique to treat patients with moderate to severe pulmonary valve stenosis. This procedure led the way to the era of pediatric catheter intervention, which has been expanded to a multitude of other lesions over the past three decades.

Figure 40.11. Schematic illustration of the balloon valvuloplasty catheter positioned across the pulmonary valve. The wire should be positioned in the distal left or right pulmonary artery.

The technique of balloon valvuloplasty is relatively straightforward (Fig. 40.11). After obtaining appropriate hemodynamic and angiographic information about severity and location of obstruction, an exchange guidewire is introduced through an end-hole catheter and positioned in the distal left or RPA. A balloon is chosen that is 20% to 30% larger than the angiographically measured pulmonary valve annulus, and it is positioned over a guidewire with the valve at its midpoint. As the balloon is inflated, a waist from the stenotic valve should be observed initially and disappear at full inflation (Fig. 40.12). In larger patients with an annulus diameter of more than 20 mm, the double-balloon technique may be necessary, with simultaneous inflation of two angioplasty balloons. A method to calculate the effective diameter of two balloons was described by Radtke et al. (22). Following balloon dilation, a careful pullback with an end-hole catheter is performed to evaluate the degree and site of any residual obstruction. Not infrequently, a gradient is measured across the infundibulum that may have been masked before valvuloplasty by the distal valvar obstruction. This type of dynamic infundibular stenosis typically resolves over time as the hypertrophied muscle regresses.

Shortly after the introduction of pulmonary valvuloplasty in children, the procedure was performed successfully in neonates with critical pulmonary valve stenosis (23). Before catheterization, these patients usually require stabilization and initiation of a prostaglandin E1 infusion to maintain ductal patency. Several of technical advances, such as the introduction of low-profile balloons, have increased the success and safety of balloon dilation in this group of patients, such that it is now considered the treatment of choice (24–26). The use of angled-tip catheters and high-torque wires has facilitated crossing the tiny pulmonary valve orifice. Initial dilation with a small coronary angioplasty balloon to enlarge the orifice and subsequent dilations with progressively larger balloons allow adequate relief of obstruction in most neonates (27). Placement of the guidewire through the patent ductus into

Figure 40.12. Lateral view of a partially inflated valvuloplasty catheter positioned across the pulmonary valve. As the balloon is inflated, a “waist” appears at the site of the pulmonary valve. This waist should be centered in the mid portion of the balloon.

the descending aorta, rather than in the LPA, allows a more stable wire position. Creating a “rail” by snaring the wire in the descending aorta can facilitate introduction of the desired balloon catheter through the orifice (Fig. 40.13) (28).

The short- and intermediate-term results of pulmonary valvuloplasty in children and adults with typical pulmonary valve stenosis have been excellent (29–33). The most comprehensive series to date reported on 533 patients with a median follow-up of 33 months and a maximum follow-up of 8.7 years (33). The morphology of the pulmonary valve was typical in 82% of patients, dysplastic in 13%, and complex (postsurgical valvotomy, associated with other significant lesions) in 5%. A good outcome, defined as a residual Doppler gradient at follow-up of 36 mm Hg or lower without the need for repeat procedures, was achieved in 77% of the total group and in 85% of those with typical valve morphology. In contrast, 65% of patients with dysplastic pulmonary valve had a suboptimal outcome. Independent predictors of suboptimal intermediate-term outcome were a small annular size (characteristic of patients with dysplastic valves), a higher immediate residual gradient, an earlier year of the initial valvuloplasty, and smaller balloon:annulus ratio (BAR) in those with typical valves. Balloons used in this study were a mean of $112\% \pm 20\%$ of the annular diameter. The latter two predictors suggest that gradient reduction, at least for typical pulmonary valve morphology, could be improved by greater experience and the use of BARs > 1.2 , as has been borne out by smaller studies (31,32). The use of excessively large balloons, however, has been associated with a higher rate of late severe pulmonary insufficiency (32,34).

Long-term outcomes have been reported on smaller series of patients with a mean follow-up of 11.9 years and a range up to 19.3 years (35). In this group of 134 patients, in whom the average BAR was 1.3, the results have been similar with persistent gradient reduction in the majority of patients and a lower success rate in those with dysplastic valves. Freedom

Figure 40.13. Schematic illustration of the technique of pulmonary valvuloplasty in a neonate as seen from the lateral projection. The guidewire was placed in the descending aorta through the patent ductus arteriosus. If necessary, the guidewire can be snared in the descending aorta to facilitate introduction of the balloon through the tiny orifice. PDA, patent ductus arteriosus; PV, pulmonary valve; RV, right ventricle. (Modified from Latson L, Cheatham J, Froemming S, et al. Transductal guidewire “rail” for balloon valvuloplasty in neonates with isolated critical pulmonary valve stenosis or atresia. *Am J Cardiol* 1994;73:713–714, with permission.)

from any reintervention at 1, 5, 10, and 15 years were 90%, 83%, 83%, and 77%, respectively. Only 17 patients had surgical intervention at some point during follow-up to relieve valvar, subvalvar, or supra-valvar obstruction, and 11 of those had dysplastic valves. Two additional children had surgical intervention for severe tricuspid regurgitation at 11 and 12 years of age. At operation, a flail anterior leaflet was found in both, possibly caused by a tear at the time of valvuloplasty. Repeat balloon valvuloplasty was performed in 11 children, 2 of whom eventually underwent surgery due to the development of subpulmonary stenosis. Risk factors for reintervention were younger age and lower body surface area, a smaller pulmonary valve annular diameter Z-score, a higher pulmonary valve gradient at the initial procedure, and the presence of Noonan syndrome. Clinical status for the entire cohort was excellent at a mean follow-up of 11.9 years, with no reported arrhythmias and only two patients in New York Heart Association (NYHA) class II.

The significantly lower success rate for patients with dysplastic pulmonary valves is not surprising given the anatomic features of these valves. The mechanism of obstruction relief in patients with typical, doming pulmonary valves has been shown to be commissural splitting in the majority of cases (36,37). In dysplastic valves, the leaflets may be markedly thickened and myxomatous with little commissural fusion. In addition, the annulus and main pulmonary artery are usually hypoplastic, further limiting the effectiveness of valvuloplasty. Several studies, however, documented adequate relief of obstruction in 35% to 65% of patients with dysplastic valves (30,32,33). Accurate predictors of success before valvuloplasty have not been identified. Thus, although controversy remains, the usual practice is to offer balloon valvuloplasty as a first

line of treatment and proceed to surgical valvotomy if balloon valvuloplasty is unsuccessful. In neonates with critical pulmonary valve stenosis, the success of pulmonary valvuloplasty at intermediate-term follow-up also has been lower than in older patients, regardless of valve morphology (24–26,34,38,39). With a mean follow-up of approximately 3 to 6 years for most studies, varying success rates have been reported, depending on how success is defined. Early in the experience, procedural failure was often due to an inability to cross the severely stenotic pulmonary valve, but with the availability of preformed catheters, better wires, and lower profile balloons, dilation can now be accomplished in nearly 100% of patients. If dilation was accomplished, immediate effective gradient reduction usually was achieved in more than 90% of patients. Despite successful relief of obstruction, 5% to 10% of these patients were unable to sustain sufficient forward flow through the pulmonary valve to maintain adequate saturations because of their severely hypertrophic, noncompliant, and sometimes hypoplastic RVs.

If discontinuation of prostaglandin E1 and subsequent ductal constriction are not tolerated immediately after valvuloplasty, these infants can be maintained on prostaglandin for as long as 2 to 3 weeks while intermittently assessing whether constriction of the ductus is tolerated with O₂ saturations remaining 70% or greater. If ductal dependency persists after that time, a surgical aortopulmonary shunt is placed. In rare instances, balloon atrial septostomy is also necessary to ensure adequate cardiac output. Neonates who remain cyanotic following valvuloplasty, with or without a surgical shunt, often demonstrate progressive resolution of their cyanosis over weeks to months as right ventricular compliance improves and the atrial right-to-left shunt diminishes. Ultimately, those in whom a shunt was created can undergo shunt closure either surgically or by transcatheter techniques. Atrial septal defect closure also may be necessary, depending on the size of the atrial communication. Recurrent valvar stenosis necessitating repeat valvuloplasty may occur within months of the initial procedure in about 10% of these patients and subsequently may afford long-term relief of obstruction.

Stenting of the ductus can be considered as an alternative to a surgical shunt in patients who remain ductal dependant following valvuloplasty. The use of a stent to maintain ductal patency was first reported in the early 1990s (40,41). Available data document gradual narrowing of the stent lumen over a period of months, during which time there is typically sufficient growth of the right heart and improved right ventricular compliance to obviate the need for ductal flow (42,43). Transcatheter techniques can also be used to close the atrial septal defect when necessary, potentially eliminating the need for any surgical intervention.

Maintaining an unobstructed pulmonary valve is important in these infants to optimize forward flow through the RV as a stimulus for growth and to allow resolution of the right ventricular hypertrophy. About 15% to 20% of neonates with critical pulmonary stenosis ultimately undergo surgical intervention to relieve either valvar stenosis resistant to dilation or subvalvar obstruction (25,26,39,44). The strongest determinant of the need for surgical intervention has been found to be the presence of subvalvar stenosis, followed by the annular dimension and morphology of the pulmonary valve. A smaller indexed tricuspid valve annulus also confers a higher risk of surgical intervention (39). In a small minority, persistent right ventricular hypoplasia precludes a two-ventricle repair.

The incidence of major complications from pulmonary valvuloplasty is exceedingly low in children and adults but is higher in infants and neonates. The largest study to date from the Valvuloplasty and Angioplasty Registry reported only two deaths from a total of 822 patients (0.2%) (29). The causes of death were laceration of the inferior vena

cava–iliac vein junction during balloon withdrawal in a 5-day-old infant and tearing of the pulmonary valve annulus during balloon inflation with a reportedly properly sized balloon in a 12-month-old infant. Other major complications occurred in three patients, including perforation of the RVOT resulting in tamponade and tricuspid regurgitation requiring surgical intervention. The incidence of minor complications was 1.3%, including vein thrombosis, vein tears, and arrhythmias. In neonates, mortality was approximately 3% and was due to various causes, including venous injury, myocardial dissection, and development of necrotizing enterocolitis. The incidence of significant morbidity in neonates was on average around 10%. Specific complications reported include wire perforation of the RVOT with or without tamponade, stroke, seizures, necrotizing enterocolitis, endocarditis, septic shock, and abrupt closure of the ductus despite prostaglandin infusion requiring urgent aortopulmonary shunt placement.

Most patients who have been treated with pulmonary valvuloplasty have some degree of pulmonary regurgitation (PR) (31–33). The incidence of moderate PR early after valvuloplasty has been variably reported as <5% to as much as 24% at intermediate-term follow-up. This relatively wide range is at least partially a result of the lack of standardized grading criteria for severity of PR. Longer follow-up and improved grading methods have shown greater degrees of PR (35,45), particularly in patients undergoing the procedure as neonates. PR has been shown to progress over time in the same group of patients (35). At a mean follow-up of 0.9 years, 22% of patients had moderate and 2% had severe PR, while at 11.9 years of follow-up, the percentage of patients with moderate PR increased to 40%, and with severe PR to 17%. Severe PR was diagnosed by echocardiogram when there was reverse flow in the branch pulmonary arteries and a nonrestrictive regurgitant Doppler signal across the RV outflow tract. Right ventricular enlargement was significantly greater in children with severe PR. Multivariate analysis identified only smaller body surface area at the time of intervention as being significantly associated with moderate or severe PR in follow-up. Moderate or severe PR developed in 74% of patients who underwent the procedure as neonates, in contrast to 44% of all other patients. Using cardiac MRI to obtain RV volumes, Harrild et al. (45) found that 34% of patients at a median follow-up of 13 years after pulmonary valvuloplasty had a PR fraction >15%, while in 17% of the cohort, the PR fraction was >30%. In this series, PR fraction was associated with younger age at dilation and with BAR, particularly when the BAR was ≥ 1.4 . The median PR fraction in patients with a BAR ≥ 1.4 was 26%. Other series have also found that a larger BAR and a higher degree of obstruction before dilation, in addition to younger age, are associated with the development of severe PR (32,44).

Compared with surgical valvotomy, patients treated with valvuloplasty appear to have less regurgitation with clinically equivalent relief of obstruction, although duration of follow-up is significantly longer for the surgical patients (31,46), and there is no contemporaneous surgical series. It is well known that significant degrees of PR with no other hemodynamically significant lesions are well tolerated for long periods. However, moderate degrees of surgically induced pulmonary insufficiency affect the normal hemodynamic response to exercise, resulting in decreased exercise capacity (47). Similarly, it has been found that patients with a PR fraction >15% following balloon dilation have decreased exercise capacity when compared to those with a PR fraction $\leq 15\%$ (percent predicted peak VO₂ $85 \pm 17\%$ vs. $96 \pm 16\%$) (45). It would seem prudent to accept mild degrees of residual stenosis as opposed to complete relief of obstruction in exchange for avoiding significant PR.

No patient outside of the neonatal group has been reported to have had pulmonary valve replacement following balloon dilation. In contrast, severe PR requiring surgery has been

reported in a handful of patients who underwent balloon valvuloplasty as neonates (34,44). In a series of 107 patients, 6 had severe PR at a mean follow-up of 7.2 years (34). All were under 2 months of age at the time of valvuloplasty and had severe or critical obstruction. The postdilation gradient was significantly lower in these six patients (8 mm Hg) than in the whole group (19 mm Hg). One underwent pulmonary valve replacement, and the remaining five are likely to have surgery during childhood. The average BAR used in these six patients was 1.44, in comparison to 1.08 for the group as a whole. Perhaps even greater caution against overly aggressive dilation should be exercised in neonates than in their older counterparts, aiming for a BAR closer to 1.2, and not exceeding 1.3 (48). This approach may lead to repeat balloon valvuloplasty in a slightly larger number of patients with critical pulmonary stenosis, but this is preferable to the need for eventual pulmonary valve replacement.

Surgical Valvotomy

Since the advent of pulmonary balloon valvuloplasty, surgical valvotomy is reserved for patients with dysplastic pulmonary valves resistant to dilation or patients with multiple levels of fixed obstruction. Valvotomy can be achieved using either a closed or open technique through the main pulmonary artery. There is often a persistent pressure gradient immediately after surgery in patients with isolated valvar pulmonary stenosis attributable to dynamic narrowing of the hypertrophied infundibulum (as also observed following balloon valvuloplasty). A reduction in this gradient occurs in the first 24 hours after surgery, and continues at a slower rate as the hypertrophy resolves over the subsequent months. In rare cases, fatal right ventricular failure occurs (suicidal RV) in the immediate postoperative period. Propanolol may be given and may differentiate dynamic from fixed obstruction. When infundibular resection is necessary, it may be accomplished through a transatrial route via the tricuspid valve.

Simple valvotomy is ineffective when the pulmonary valve is dysplastic. Partial or more often total removal of the pulmonary valve may be necessary. In addition, insertion of a transannular patch may be necessary to enlarge the hypoplastic annulus and main pulmonary artery. These patients are usually left with at least moderate PR, which is well tolerated in medium-term follow-up. However, it is now increasingly recognized that the long-term effects of significant PR are more harmful than previously suspected (44–47,49).

Long-term relief of obstruction after pulmonary valvotomy is excellent, and restenosis is uncommon (50). The second natural history study of patients with pulmonary stenosis demonstrated that 96% of surgically treated patients remained free of reoperation for 10 years. The incidence of postoperative PR is between 57% and 90% (50–52) and is classified as moderate to severe in 28% by echocardiographic estimation (50). Despite the presence of PR in most patients, 25-year survival is excellent at 97%, and 97% of surviving patients are in NYHA class I (50). As mentioned previously, formal exercise testing has shown a tendency toward mildly decreased exercise tolerance. There is also a higher incidence of ventricular ectopy associated with exercise for postoperative pulmonary stenosis patients when compared to age-matched normal subjects (53).

Longer-term follow-up has been reported in a smaller group of 53 patients followed at a large tertiary care center, but not necessarily operated at that same institution (46). At a mean follow-up of 33 years, 53% of patients underwent reintervention, most commonly pulmonary valve replacement for free PR. A significant increase in the percentage of patients needing reintervention was noted after 25 years of follow-up. Though 50% of patients were free from reintervention at 40 years, 80% required repeat surgery by 45 years of follow-up.

Univariate analysis identified closed pulmonary valvotomy at initial repair as the only factor predictive of the need for reintervention. Overall 40% of patients underwent pulmonary valve replacement at a mean interval of 33 years after the initial surgery. All of the remaining patients who had not undergone reoperation had PR, graded as moderate or severe in 70%. The unoperated group had a shorter duration of follow-up, suggesting that with longer follow-up, many more would also require pulmonary valve replacement.

The incidence of arrhythmias in postoperative pulmonary stenosis patients was higher with longer follow-up than previously reported, with 38% of patients suffering from atrial arrhythmias and 6% with ventricular arrhythmias (46). Survival at a mean follow-up of 33 years was excellent with only two patients (3.8%) dying suddenly. Both had untreated atrial fibrillation, but neither had significant right ventricular dilation or a prolonged QRS complex on electrocardiography. Functional status was quite good, although again there was some decline with longer-term follow-up. Of the 53 patients, 82% were in NYHA class I, 16% in class 2, and 2% in class III at last follow-up. These findings must take into consideration the possibility of referral bias in this large tertiary care center.

Indications for Either Pulmonary Valvotomy or Pulmonary Balloon Valvuloplasty

Pulmonary valvuloplasty is currently the first line of treatment for pulmonary valve stenosis at any age and, most would agree, for any valve morphology. Valvuloplasty should be performed in any symptomatic patient as soon as the diagnosis is made. Infants with critical pulmonary valve stenosis also should undergo immediate valvuloplasty, but, if this is unsuccessful, surgery should be performed without delay.

Even asymptomatic patients with severe obstruction should be treated semiselectively with valvuloplasty shortly after diagnosis. With the currently available low-profile balloons, there is little benefit to waiting for the patient to reach a certain size. On the contrary, the progression of infundibular hypertrophy that may occur while waiting could make the procedure technically more difficult and prolong the duration of right ventricular hypertension following relief of the valve stenosis. Patients with moderate obstruction should undergo elective valvuloplasty if the right ventricular pressure is 50% systemic or higher. No intervention is necessary for patients with mild obstruction. They should not be restricted in their physical activity and should be treated like normal children. Endocarditis prophylaxis is not recommended for patients with pulmonary valve stenosis (54).

Assessment of Severity, Course, and Prognosis

The course and prognosis of patients with valvar pulmonary stenosis and intact ventricular septum are determined primarily by the severity of the obstruction. Symptoms are unreliable in reflecting hemodynamic severity because they usually are seen only in patients with severe or critical obstruction. Severity of stenosis is best determined noninvasively by 2-D echo-Doppler techniques. Cardiac catheterization is performed when the obstruction is deemed severe enough to require balloon valvuloplasty.

Mild pulmonary valve stenosis is generally defined as a gradient of <30 to 35 mm Hg across the valve and a right ventricular pressure less than half the left ventricular pressure. The course of mild stenosis is benign, and no intervention is required. The hemodynamic response to exercise in these patients is normal (55). No deaths occurred during a 4- to 8-year follow-up of 214 patients with mild pulmonary stenosis (56). Of 261 patients with gradients <40 mm Hg included in

the First Natural History Study, only three had progression of gradients to 60 mm Hg or more after a 4- to 8-year follow-up (51). The Second Natural History Study documented that patients with gradients <25 mm Hg do not experience an increase in gradient (50). One exception to these findings is in young infants with mild pulmonary stenosis, defined as an echo gradient of <40 mm Hg (57). Of 56 patients younger than 1 month of age with mild obstruction, 16 (29%) progressed to moderate or severe stenosis, and half of those did so in the first 6 months of life. Although in some of those neonates, the physiologic decrease in pulmonary vascular resistance may have accounted for the perceived progression, worsened anatomic obstruction seemed to occur in some.

Controversy exists over the course and prognosis of patients with moderate pulmonary valve stenosis. Most available data suggest that infants and children with moderate stenosis may develop progressively greater outflow tract obstruction, especially during periods of rapid growth (51,56). Patients with gradients between 50 and 79 mm Hg enrolled in the First Natural History Study (51) had excellent survival when evaluated as part of the Second Natural History Study (50) 20 years later, whether managed medically or surgically. By completion of the Second Natural History Study, most of these patients had surgery. In the same study, the likelihood of having surgery for patients with gradients of 25 to 49 mm Hg was about 20%. Despite the absence of symptoms in most patients with moderate pulmonary valve stenosis, formal exercise testing demonstrated subnormal cardiac output response and abnormal increase in right ventricular end-diastolic pressure, especially in adult patients, suggesting that both systolic and diastolic dysfunction may be caused by long-standing moderate obstruction (55). Currently, most centers recommend elective balloon valvuloplasty for patients with Doppler gradients of 40 mm Hg or greater.

Children with severe stenosis commonly develop increasingly severe obstruction, which may result from disproportionate growth of the child relative to the pulmonary valve. Exercise hemodynamics in children and adults with severe obstruction before and after valvotomy suggest that irreversible changes in cardiac function can develop if treatment is delayed beyond childhood. Children and adults with severe stenosis have a lower stroke index at rest and during exercise than patients with milder disease. They also have higher right ventricular end diastolic pressure at rest that abnormally increases with exercise (55). Following valvotomy in young patients, there is an improvement in stroke index and reduction in right ventricular end diastolic pressure at rest and during exercise within 1 year of operation. In contrast, this improvement is not observed in older patients, implying that permanent changes, such as myocardial fibrosis, have occurred (58,59). Hence, relief of severe pulmonary valve stenosis without undue delay is recommended.

The incidence of morbid events, such as bacterial endocarditis, in patients with pulmonary valve stenosis is quite low (50). Of 592 patients enrolled in the First Natural History Study and followed through the Second Natural History Study, only 1 patient developed endocarditis (60). Antibiotic prophylaxis is no longer recommended regardless of treatment, unless a prosthetic valve has been implanted. In such a case, prophylaxis should be used during any episodes of probable bacteremia for life (54).

Indications for Pulmonary Valve Replacement for Induced Pulmonary Insufficiency Following Relief of Pulmonary Valve Stenosis

The indications for pulmonary valve replacement for induced PR remain controversial, but most would agree that selected patients benefit from insertion of a competent pulmonary

valve (61,62). Most of the available data on the effects of long-standing PR, and the outcomes after pulmonary valve replacement, have been derived from patients with repaired tetralogy of Fallot (63–66). Limited information on the natural history of isolated congenital pulmonary valve regurgitation also documents eventual development of symptoms, particularly after age 40, as well as premature death from pulmonary valve regurgitation in a handful of patients (49). Current criteria for intervention typically include (a) the presence of symptoms such as progressive decrease in exercise tolerance or functional class or evidence of right heart failure; (b) progressive right ventricular enlargement, often accompanied by increasing tricuspid insufficiency due to annular dilation; and (c) development or progression of atrial and/or ventricular arrhythmias (46,61). Most would agree that intervention should precede significant right ventricular systolic dysfunction, which would likely be irreversible despite pulmonary valve replacement. The argument against prophylactic early replacement of the pulmonary valve centers primarily on the lack of an excellent, long-lasting prosthetic valve. Because of the eventual need for reoperation after surgical insertion of a prosthetic valve in the majority of patients, the aim is to wait as long as possible before replacing the valve, but not so long that irreversible injury to the RV has occurred.

Until recently, pulmonary valve replacement required open heart surgery under cardiopulmonary bypass. Various prosthetic valves have been used including homograft valves, xenograft valves, pericardial valves, and mechanical valves. All of these have been shown to have a limited life span due to calcification or intimal proliferation causing stenosis and/or regurgitation (64,67). Percutaneous pulmonary valve replacement with a bovine jugular venous valve sutured inside a stent was first described in a human in 2000 (68), and after refinements in the valve design and delivery system over the past decade, the procedure can now be offered to a subset of patients with an already existing prosthetic RV to pulmonary artery conduit (Video 40.3). It is not suitable for patients with a native or patched RVOT at the time of this writing. The Melody percutaneous pulmonary valve (Medtronic Inc., Minneapolis, Minnesota), as the prosthesis is named, consists of a bovine jugular venous valve sawn to a platinum-iridium balloon expandable stent that can be dilated to a diameter of 18, 20, or 22 mm. Children weighing at least 20 kg can undergo implantation of the valve, which requires a 22 Fr delivery system. In order to accommodate the valve and ensure proper function, the conduit must have a waist of 14 to 20 mm on balloon sizing in the catheterization laboratory prior to valve insertion.

At the time of this writing, over a thousand Melody valves have been implanted worldwide, and the valve is approved in the United States under HDE guidelines. The largest group of patients undergoing the procedure is postoperative tetralogy of Fallot patients who have had one or more surgical pulmonary valve replacement(s) (69). The valve has performed well with 70% freedom from reoperation at 70 months in a series that includes the learning curve from the first 50 patients (70). Further improvement in these results is expected with better patient selection and modifications in the valve design. A potentially lethal though rare complication is coronary artery compression by the valve stent. Careful assessment of the coronary anatomy in the catheterization laboratory while maintaining a fully inflated balloon at the site of planned implantation should identify patients at risk, in which case the valve would not be implanted. Conduit rupture may also occur in rare cases, and can be treated with insertion of either a covered stent or the Melody valve itself that is a covered stent, but urgent surgical intervention may be required (71). Very few deaths have occurred with Melody valve insertion and most have been related to coronary artery compression, which should be avoidable with the currently recommended protocol.

A mild increase in pressure gradients has been observed over time, while the valve has remained remarkably competent even in patients followed as long as 5 to 10 years. Fractures of the valve stent felt to be due to compressive forces can result in stenosis (72,73). This problem is likely to be reduced by the current practice of pretesting the conduits prior to valve implantation when recoil is observed during balloon dilation (74,75). A second Melody valve can be implanted in patients who develop obstruction requiring reintervention (72,76).

The Edwards SAPIEN valve, which is the same device as the Cribier Edwards transcatheter aortic valve, is another percutaneous pulmonary valve for which there is a much smaller clinical experience at this time (77). This valve consists of three bovine pericardial leaflets sawn to a stainless steel balloon expandable stent, and is available in 23- and 26-mm diameters. It also requires implantation within a prosthetic conduit. At a median follow-up of 10 months for seven patients reported in 2010, the valves were functioning well with no stent fractures (78). A feasibility trial has been completed in the United States, but HDE status has not yet been granted.

Currently, only about 15% of patients with pulmonary valve dysfunction can benefit from transcatheter pulmonary valve insertion, namely those with prosthetic conduits that meet the size requirements described previously. New technology in valve design will hopefully make the procedure available to the larger group of patients with native outflow tracts in need of a functional pulmonary valve (79,80).

To date, surgical pulmonary valve replacement for induced PR has not universally been shown to improve right ventricular hemodynamics or functional capacity, and there are no data addressing long-term survival (63,65). Similarly, following percutaneous pulmonary valve implantation, RV end diastolic volume decreased significantly in patients who underwent the procedure for either pulmonary stenosis or regurgitation, but RV ejection fraction improved only in the group with pulmonary stenosis. In those with regurgitation, the RV ejection fraction did not change either at 1 month or at 1 year of follow-up. Moreover, functional capacity measured by cardiopulmonary stress testing improved significantly in the pulmonary stenosis group by 1 month after valve implantation, and the improvement was sustained at 1 year. Patients with PR had no improvement in their functional capacity at either 1 month or 1 year after valve insertion (81). It has been argued that the current criteria for intervention may be too conservative, with some patients already having irreversible disease. The availability of a percutaneous method to replace the pulmonary valve may allow a more aggressive approach, and result in improved outcomes in selected patients.

Recently published guidelines recommend endocarditis prophylaxis after either surgical or percutaneous pulmonary valve replacement (54).

PULMONARY VALVE STENOSIS IN YOUNG ADULTS

The vast majority of patients with pulmonary valve stenosis present during childhood. If the diagnosis is not made in childhood, adult patients with hemodynamically significant pulmonary valve stenosis tend to be more symptomatic than their younger counterparts (82). Not infrequently, there is concomitant infundibular stenosis due to muscular hypertrophy in response to long-standing valvar obstruction. There may also be tricuspid insufficiency with severe pulmonary valve stenosis and right ventricular failure. In such cases, and in any symptomatic patient, intervention should be performed at lower gradients than generally accepted, since decreased flow through the valve from low cardiac output may mask severe stenosis.

As in children, balloon dilation of the pulmonary valve is the treatment of choice (83). In patients with a large annulus, the double-balloon technique may be utilized, but it is not always necessary to use a balloon larger than the annular diameter when the annulus is very large. A 25-mm-diameter balloon should suffice for most patients with typical pulmonary valve morphology. Acutely, right ventricular hypertension may persist due to infundibular hypertrophy and/or spasm after dilation, and some operators favor temporary treatment with beta-blockers in severe cases (84). Long-term results are excellent, and regression of infundibular stenosis over time is well documented (83,85,86). PR has not been reported to be a significant issue, but rigorous long-term assessment is lacking. Percutaneous pulmonary valve implantation can now be performed in adults with stenotic or regurgitant RV to pulmonary artery conduits following the guidelines described previously.

SUBVALVULAR RIGHT VENTRICULAR OUTFLOW TRACT OBSTRUCTION

Primary subpulmonary stenosis with intact ventricular septum, described by Elliotson (87) in 1830, accounts for only about 5% of all cases of RVOT obstruction. This entity has been separated into two types. One type consists of an obstructive fibrous band or bands at the junction of the main right ventricular cavity and the proximal infundibulum, often referred to double-chambered RV or right ventricular muscle bundles. In the second type, narrowing of the infundibulum itself is due to fibromuscular thickening of the infundibular wall, which may extend from immediately below the pulmonary valve to the proximal infundibulum. Infundibular stenosis is more commonly associated with tetralogy of Fallot or pulmonary valve stenosis. The physiologic and clinical manifestations of infundibular stenosis are almost identical to those for double-chambered RV. Infundibular stenosis associated with pulmonary valve stenosis may improve spontaneously over time after balloon pulmonary valvuloplasty but double-chambered RV tends to worsen with age (86).

RIGHT VENTRICULAR OBSTRUCTION

Double-Chambered Right Ventricle

This congenital malformation, known as “double-chambered RV,” is characterized by aberrant hypertrophied muscular bands that divide the right ventricular cavity into a proximal high-pressure chamber and a low-pressure chamber distal to the hypertrophied muscle bands.

Pathology

Anatomically, the anomalous hypertrophied muscle bundles constitute a pyramidal mass of muscle that runs between the ventricular septum inferior to the insertion of the septal leaflet of the tricuspid valve to the anterior wall of the RV. There are usually two bundles: the ventral bundle, which attaches to the wall of the RV adjacent to the septum, and the dorsal bundle, which is larger and attaches to the base of the anterior papillary muscle (Fig. 40.14). The right ventricular cavity is divided into a proximal chamber, which consists of the sinus portion of the RV, and a distal chamber, which consists of the infundibulum. In tetralogy of Fallot, the obstruction involves the infundibular area, but the anomalous muscle bundles in double-chambered RV cross the right ventricular cavity and lie proximal to the infundibulum. The orientation of these

Figure 40.14. Right ventricular angiogram of a child with double-chambered RV. **A:** Anteroposterior projection demonstrates the anomalous muscle bundle (AMB) dividing the RV horizontally into inflow (RV_i) and outflow (RV_o) portions. **B:** The anomalous muscle bundle and inflow and outflow chambers also are well seen on the lateral projection. A small VSD is faintly opacified.

bundles differs from that of the moderator band. The septal attachment of the moderator band is usually in the apical third of the ventricular septum, whereas in anomalous muscle bundles, the septal attachments are near the base of the tricuspid valve ring. Although both types of muscle bundles attach to the anterior wall of the RV, the moderator band lies toward the septum and does not ordinarily obstruct the cavity.

The origin of these anomalous bundles is unknown. It is believed that they may be due to a localized growth of the trabeculated myocardium early in development. It also has been suggested that the right ventricular subdivision and obstruction in this malformation represent an arrested incorporation of the primitive bulbus cordis into the right ventricular body (88). The improper expansion of the bulboventricular junction would therefore result in incomplete fusion of the bulbar and endocardial cushion elements that normally close the superior portion of the ventricular septum, which could explain the frequent association of a VSD with this malformation. The VSD is most frequently found in the perimembranous septum and occasionally in a subarterial location (89). Discrete subaortic stenosis also can occur with this lesion, supporting the concept of inadequate bulbar incorporation as an etiologic mechanism.

Physiology

The anomalous muscle bundles may cause varying degrees of obstruction within the RV, and the severity of obstruction often will increase with time (90). Often nonobstructive anomalous muscle bundles in infancy become obstructive later. For blood to pass from the right ventricular inflow to the right ventricular outflow, it must course either above the muscle bundles, between the muscle bundles and the tricuspid valve, or through the narrow channel between the bundles and septal wall. During ventricular systole, the diameter of these channels is usually markedly reduced. The hemodynamic consequence of the obstruction is an elevated pressure within the proximal or sinus portion of the RV.

Manifestations

Clinically, patients with anomalous muscle bundles and intact ventricular septum closely resemble patients with isolated pulmonary valvar stenosis. When a VSD is present, the clinical features may be dominated by the ventricular septal defect.

A loud pansystolic crescendo-decrescendo murmur, often accompanied by a thrill, is heard at the left sternal border. The murmur may be indistinguishable from that of isolated valvar pulmonary stenosis, but a click is not audible, and the pulmonary valve closure sound may not be as delayed or as soft as one would expect with a murmur of similar intensity in valvar pulmonary stenosis. The chest radiograph is similar to that from other types of RVOT obstruction, unless a significant VSD is present. In most patients, the electrocardiogram shows right ventricular hypertrophy, but may show evidence of diminished terminal right ventricular forces. In a report involving 30 patients with double-chambered RV, an upright T wave in V3R was the only finding suggestive of right ventricular hypertrophy in approximately 40% of the cases (91).

Two-dimensional echocardiography is usually diagnostic in this lesion. The anomalous muscle bundles can be visualized best from either the subcostal or parasternal views (Fig. 40.15). Severity of obstruction can be assessed by the degree of anatomic narrowing and by Doppler interrogation of the obstructed region. Color-flow Doppler identifies the site of obstruction by the appearance of a mosaic pattern where the high-velocity flow originates (Fig. 40.15). In addition, the presence or absence of a VSD can be documented. Abnormal fluttering of the pulmonary valve is often a concomitant finding.

Cardiac Catheterization

Cardiac catheterization is sometimes performed to confirm the diagnosis of double-chambered RV. The catheter must be placed in the inflow portion of the right ventricular cavity, and

Figure 40.15. A: Subcostal view of the RV from a patient with double-chambered RV. The anomalous muscle bundle (MB) courses obliquely across the RV. B: Color-flow Doppler through the obstructing MB has a mosaic pattern consistent with high-velocity flow. PV, pulmonary valve; R, right; S, superior.

a pressure gradient is demonstrated as the catheter is further advanced into the distal, low-pressure chamber. The pressure in the distal chamber is usually equal to that in the pulmonary artery unless there is associated pulmonary valve stenosis. Care must be taken first to place the catheter into the right ventricular apex, because it is relatively easy to advance the catheter from the right atrium directly to the RVOT and “miss” the gradient. If a VSD is present, the location and resultant shunt should be determined.

Angiocardiography

Right ventricular angiography is an excellent method to demonstrate the anatomy of this lesion and always should be performed when a significant intraventricular pressure gradient is detected. Anterior and lateral projections demonstrate filling defects within the RV below the crista supraventricularis, between the outflow and inflow areas (Fig. 40.14). Left ventriculography also can be performed if there is a question about an associated VSD or, less commonly, subaortic stenosis.

Magnetic Resonance Imaging

The role of MRI as a diagnostic tool in congenital heart disease has increased significantly over the past decade. Its role is particularly important in adult patients, in whom echocardiographic views are often limited, and who can best cooperate with the testing requirements of MRI to obtain optimal images. The anatomic features of double-chambered RV can be readily recognized by MRI (92), and it is even possible to obtain a quantitative assessment of the severity of obstruction by measuring flow velocities. MRI is likely to be superior to echocardiography in the older patient, and may obviate the need for cardiac catheterization in most patients.

Treatment

The treatment of this type of obstruction is usually surgical. Every effort should be made to define the anatomy correctly before surgery. Certain characteristic features of this condition seen at surgery have been described (93). During ventricular contraction, a visible “dimple” in the ordinarily smooth right ventricular surface strongly suggests the presence of an obstructing muscle bundle. The dimple deformity usually is found near the anterior intraventricular groove about midway between the base and the apex of the heart, and it corresponds to the parietal attachment of the ventral limb of the anomalous muscle bundle. A right ventriculotomy is usually not necessary to visualize the obstructing muscle mass adequately. The best approach is typically through the tricuspid valve. The papillary muscle attachments to one or the other end of the trabeculum can be fully defined. Usually, one end or the other of the trabeculum can be divided. Occasionally, it must be left intact and channels in front and behind enlarged. A search for a VSD always should be carried out because of the frequent association of these two lesions (89). Stenting of the stenotic region in two high-surgical-risk patients with comorbidities has been reported. Results were favorable in the short term, but concerns about long-term stent integrity will need to be evaluated in a larger group of patients before this approach can be considered a reasonable alternative to surgery in standard risk patients (94).

Course and Prognosis

Double-chambered RV appears to be a progressive disease with gradually increasing severity of obstruction from the anomalous muscle bundles. As the obstruction worsens, an associated VSD may become progressively smaller or close spontaneously. Cases presenting with intact ventricular septum may in fact have had spontaneous closure of a ventricular septal defect. Long-term follow-up to 20 years after repair

of double-chambered RV demonstrated only mild residual sequelae, and serious cardiac compromise has been infrequent (89,90,95). The residual lesions have included mild right ventricular outflow obstruction, insignificant residual VSDs, tricuspid regurgitation, and the presence of aortic valve regurgitation. The need for reoperation for recurrent obstruction is exceedingly uncommon if adequate resection of the anomalous bundles is achieved (89).

DOUBLE-CHAMBERED RIGHT VENTRICLE IN ADULTS

Double-chambered RV is usually diagnosed and surgically corrected in childhood because patients come to medical attention with a loud systolic murmur. Left untreated, the severity of the obstruction in double-chambered RV tends to become progressively worse into adulthood. Patients with this lesion who first come to attention as adults tend to have higher pressure gradients than children and are very frequently symptomatic (96,97). The most common symptom is dyspnea on exertion, but angina, syncope, and right heart failure have been reported. Many adult patients have a perimembranous VSD but little left-to-right shunting because the VSD connects to the high-pressure inflow part of the RV. The systolic murmur in these patients is therefore predominately due to the right ventricular outflow narrowing rather than the VSD. Up to 40% of adults may have mild aortic insufficiency secondary to either aortic valve prolapse into the VSD or mild subaortic stenosis (which can create turbulence and deformity of the aortic valve). Endocarditis has been reported in a number of older patients with this condition. Surgical repair in adults may be more likely to require a transventricular incision. Surgery usually improves the clinical status of symptomatic adults, and later development of recurrence, worsening aortic regurgitation, or arrhythmias is rare (96,97). Patients who undergo surgical repair in childhood appear to do very well as adults, but infrequent follow-up is recommended with surveillance for arrhythmias, valve dysfunction, and ventricular dysfunction.

PERIPHERAL PULMONARY ARTERY STENOSIS WITH INTACT VENTRICULAR SEPTUM

Stenosis of the pulmonary arteries, isolated or in association with other cardiac defects, occurs in 2% to 3% of all patients with congenital heart disease. The stenosis may be single, involving the main pulmonary artery or either of its branches, or multiple, involving both the main and several smaller peripheral pulmonary artery branches (98).

Isolated peripheral pulmonary artery stenosis was described first by Maugars (99) and later by Schwalbe (100), and numerous reports have followed since. Other associated cardiac defects, most commonly valvar pulmonary stenosis and VSD, are present in about two-thirds of the cases. Hypoplasia of the pulmonary arteries also is seen frequently with tetralogy of Fallot. Peripheral pulmonary stenosis is often seen as a feature of several congenital syndromes. In the syndrome of congenital rubella, peripheral pulmonary artery stenosis typically is associated with patent ductus arteriosus and atrial septal defect. The association of supravalvar aortic stenosis, multiple peripheral pulmonary artery stenosis, mental retardation, and peculiar facies has been described as Williams syndrome (101). Peripheral pulmonary artery stenosis also is associated with Noonan syndrome, Alagille syndrome, cutis

laxa, Ehlers-Danlos syndrome, and Silver-Russell syndrome. Although rare, familial and nonfamilial cases of isolated peripheral pulmonary stenosis with no underlying syndrome also have been described (102).

Embryology and Pathology

The pulmonary artery and its branches developmentally have their origin from three separate vascular components. The proximal portion of the main pulmonary artery just above the semilunar valve probably is derived from the bulbus cordis. The remainder of the trunk of the main pulmonary artery arises from the common truncus arteriosus. The proximal segments of the right and left branch pulmonary arteries are derived from the sixth branchial arches on either side. The distal portion of the right sixth arch disappears completely, whereas the one on the left persists as the ductus arteriosus and later as the ligamentum arteriosus. The peripheral portions of the pulmonary artery branches derive from the postbranchial pulmonary vascular plexus, which lies in close relationship to the growing lung buds.

The pathogenesis of peripheral pulmonary artery stenosis is not completely understood but probably differs with the underlying process. It appears that multiple factors and many types of pathologic changes may produce narrowing of the branch pulmonary artery. When pulmonary artery stenosis is associated with significant intracardiac anomalies, the pathogenesis is likely to be developmental in origin. Certain teratogenic agents may interfere with the development of any of the components of the pulmonary arterial tree and may lead to atresia, hypoplasia, or stenosis. At least one such agent, the rubella virus, appears to exert its teratogenic effect by interfering with the normal formation of the elastic tissues. Relatively discrete branch stenosis can be seen in association with ductal closure, especially in cyanotic heart disease.

Specific genetic abnormalities underlying many of the syndromes associated with isolated peripheral pulmonary artery stenosis are being increasingly recognized. A genetic deletion mapped to chromosome 7 resulting in abnormal elastin production was found in most patients with Williams syndrome (103). A deletion in chromosome 20 appears to be responsible for Alagille syndrome, but the resulting biochemical abnormality has not been identified (104). Several families with multiple relatives affected with Noonan syndrome have had the genetic mutation mapped to chromosome 12, and missense mutations in a specific gene on this chromosome are now known to account for more than 50% of cases (9,105). These genetic abnormalities can arise as sporadic mutations or can be familial with autosomal dominant inheritance.

A useful classification of peripheral pulmonary artery stenosis was proposed by Gay et al. (98) (Fig. 40.16). They classified the stenoses into four types: stenoses involving the main pulmonary trunk or the right and left branches, stenoses involving the bifurcation of the pulmonary artery extending into both branches, multiple peripheral stenoses, and a combination of main and peripheral stenoses. In approximately two-thirds of cases, the stenoses involved the main pulmonary trunk, its bifurcation, or its main branches. When the stenosis is localized, dilation of the vessel distal to the narrowing is usually present. With long segment constrictions, only minimal poststenotic dilation, if any, is seen, and no dilation at all is noted with the hypoplastic form. The main pulmonary trunk usually is not dilated, even with severe stenosis involving its distal portions or with bifurcation and branch stenosis. Mild degrees of prestenotic dilation are seen occasionally, but never to the extent seen in obstructive pulmonary hypertension.

Figure 40.16. Classification of pulmonary artery stenosis. (From Gay BB, Franch RH, Shuford WH, et al. Roentgenologic features of simple and multiple coarctations of the pulmonary artery and branches. *Am J Roentgenol* 1963;90:599, with permission.)

Physiology

The physiology associated with peripheral pulmonary artery stenosis results in elevations of right ventricular and pulmonary artery (proximal to stenosis) systolic pressure that depends on the severity and distribution of the stenoses. In most cases, the obstruction is central and results in a limited volume capacity of the pulmonary trunk proximal to the obstruction. When the obstruction is severe, right ventricular ejection is prolonged, and the pulmonary artery trunk proximal to the obstruction behaves as an extension of the RVOT. The pulmonary arterial pressure proximal to the obstruction is the same as that of the RV, and the pulmonary valve remains open as long as there is a systolic pressure gradient between the RV and the distal pulmonary artery. This explains the delay in pulmonary valve closure despite the high systolic pressure in the pulmonary tree. The pressure tracing proximal to the stenosis resembles that of the RV, with high systolic and low diastolic pressure. In cases of severe multiple peripheral pulmonary stenoses involving many small branches, closure of the pulmonary valve occurs early and approximates closure of the aortic valve. When the stenosis is unilateral and there is no left-to-right shunt, resting right ventricular pressure remains normal. In such cases, the normal contralateral pulmonary arterial tree can accommodate the cardiac output without an increase in pressure. Because flow to the stenotic side is lower than normal, the systolic pressure difference tends to underestimate the severity of obstruction;

however, the diastolic pressure difference between the main pulmonary artery and the stenotic branch is proportional to the severity of obstruction. Measurement of flow distribution, rather than pressure gradients, is the best way to assess relative stenosis in the pulmonary branches. Relative flow to the various regions of the lungs can most easily be measured by quantitative radionuclide pulmonary perfusion scans or by MRI.

Manifestations

Clinical Features

Patients with mild or moderate bilateral pulmonary artery stenosis, as well as those with unilateral stenosis, are usually asymptomatic. Dyspnea on exertion, easy fatigability, and signs of right heart failure may occur in patients with severe obstruction. Several auscultatory findings differentiate pulmonary artery stenosis from other right-sided obstructive lesions. The first heart sound is usually normal, and there is no ejection click. The second sound is usually normally split and of normal or slightly increased intensity. There is a systolic ejection murmur in the pulmonary area that is well transmitted to the axilla and back. A continuous murmur occasionally may be present, indicating that the diastolic gradient across the obstruction is significant. In patients with multiple peripheral pulmonary artery stenoses, the second sound in the pulmonary area may be so loud that pulmonary hypertension is suspected.

The presence of soft, blowing systolic or continuous murmurs typically heard over both lung fields and in the back should point to the correct diagnosis.

Electrocardiographic Features

The electrocardiogram is normal in patients with mild stenosis and demonstrates right ventricular hypertrophy in those with moderate to severe obstruction. A relatively high frequency of left axis deviation has been noted in infants with the rubella syndrome and peripheral pulmonary artery stenosis, as well as in infants with Noonan syndrome.

Radiologic Features

The chest radiograph in patients with unilateral or bilateral pulmonary artery stenosis is almost always normal. There must be severe unilateral stenosis, and often an associated left-to-right shunt lesion, for there to be a detectable difference in the degree of vascularity between the two lung fields. When the stenosis is bilateral and severe, right atrial and right ventricular enlargement may be seen. MRI is becoming increasingly useful in detailing pulmonary artery anatomy. It is superior to echocardiography and complementary to angiography for the detection of pulmonary artery abnormalities. Radionuclide lung perfusion scans are very useful in quantifying flow to each lung before and after surgical or transcatheter therapy.

Echocardiographic Features

The anatomy of the proximal pulmonary arteries usually can be delineated fairly well by echocardiography, but the distal pulmonary arteries cannot be imaged reliably. The parasternal short axis view and suprasternal views are the most helpful (Fig. 40.17). Color-flow Doppler can contribute to the qualitative assessment of stenosis by the appearance of turbulence at

Figure 40.17. Suprasternal notch short-axis view from an infant with Williams syndrome and mild proximal right pulmonary artery (RPA) and left pulmonary artery (LPA) stenosis. The proximal branches are well seen, but the peripheral branches cannot be well imaged. AO, aorta; MPA, main pulmonary artery; R, right; S, superior.

the area of obstruction. The pressure gradient can be estimated by Doppler but not always accurately. The echocardiogram is useful in detecting secondary manifestations of right ventricular hypertension, such as right ventricular hypertrophy, tricuspid insufficiency, or enlargement of the right-sided chambers.

Cardiac Catheterization

The clinical suspicion of peripheral pulmonary stenosis may require cardiac catheterization to confirm the diagnosis and determine the severity and exact anatomy. Carefully obtained withdrawal pressure tracings from the distal branches will demonstrate pressure gradients across the stenotic segments (Fig. 40.18). Systolic pressure gradients higher than 10 mm Hg should be considered abnormal in the absence of a left-to-right shunt with increased pulmonary blood flow. When the stenosis is unilateral, a pressure gradient is present at the site of obstruction, but the proximal pulmonary artery pressure is normal. The measured gradient may underestimate the severity of angiographic obstruction as a result of preferential flow to the unobstructed side. Physiologic gradients >10 mm Hg may be recorded in young infants, especially premature infants, between the pulmonary branches and the main trunk due to the size discrepancy between the two. Artifactual gradients may be created by an overly large catheter in a small vessel.

With bilateral pulmonary artery stenosis, the pressure tracing proximal to the obstruction has characteristic features (Fig. 40.18). The systolic portion of the tracing is identical to that of the RV. The diastolic notch is usually quite low with a slow descent, followed by low diastolic pressure similar to that distal to the obstruction. The pulse pressure is wide and increases with increasing severity of obstruction. These characteristics are attributed to the altered function of the pulmonary trunk, which becomes an extension of the RVOT. The wall of the pulmonary trunk is usually thick and fibrotic with reduced elasticity. As long as pulmonary artery pressure distal to the obstruction is lower than the right ventricular pressure, the pulmonary valve remains open. Closure of the valve occurs during the early phase of isometric relaxation of the ventricle, which results in a sudden increase in the volume capacity of the pulmonary trunk with a corresponding fall in pressure and formation of the diastolic notch. The slow descent of the diastolic pressure is a consequence of the distal obstruction and the impaired elastic recoil of the main pulmonary trunk. When there is associated valvular stenosis, the severity of peripheral pulmonary artery stenosis may be difficult to determine by pressure measurements but can be assessed by angiography and flow scans.

Angiocardiography

Angiocardiography is the best tool for the assessment of anatomic features of peripheral pulmonary artery stenosis. The exact location, extent, and distribution of the lesions can be easily visualized with selective injections proximal to the site of obstruction (Fig. 40.19). The anterior view with cranial angulation and straight lateral views usually show the anatomy of the RPA and of the peripheral branches bilaterally (Fig. 40.20). The proximal left main branch can be well visualized in the hemiaxial left anterior oblique and sometimes lateral views. The main pulmonary trunk is usually normal or hypoplastic. In severe unilateral obstruction, delayed filling of the respective pulmonary vein may be noted.

Noninvasive Imaging: Magnetic Resonance Imaging and Computed Tomography

Advances in noninvasive radiologic imaging modalities in the last decade have allowed excellent visualization of the pulmonary artery anatomy by these techniques, often complementing,

Figure 40.18. Pressure tracing during withdrawal of an end-hole catheter from distal right pulmonary artery (RPA) to proximal right pulmonary artery in a child with severe RPA stenosis. The pressure increases abruptly as the stenotic segment is crossed. Note the slow terminal descent and low diastolic pressure in the proximal RPA. Note also that there is no gradient between the proximal RPA pressure and right ventricle pressure (RVP).

and sometimes replacing, angiography. Gadolinium-enhanced 3-D magnetic resonance angiography (MRA) has been shown to correlate with angiographic findings with 100% sensitivity and specificity when assessing pulmonary artery stenosis or hypoplasia, absent or discontinuous pulmonary arteries (106). Measurements of pulmonary artery diameter also showed excellent correlation, with a mean difference of 0.5 ± 1.5 mm between the two modalities. A limitation of MRA for pediatric patients is motion artifact requiring breath-holding for optimal image acquisition. General anesthesia and suspending mechanical ventilation may be necessary in very

young patients. Anatomic delineation of the more peripheral branches, typically beyond the third and fourth generation, is not adequately achieved by MRA. Advantages of MRA over angiography include reduced risk, avoidance of radiation, and preservation of vascular access for future interventional procedures. Electron-beam computed tomography (CT) has also shown excellent correlation with angiography (107). It is less sensitive to motion artifact and can often be performed with sedation alone, even in small infants. CT is more suited for the unstable patient because of the short time needed to acquire the information, and has better spatial resolution than MRA.

Figure 40.19. Selective right and LPA angiograms of an 8-year-old girl with severe bilateral pulmonary artery stenosis and no other associated cardiac or systemic disease. **A:** Anterior view of the right pulmonary artery demonstrates long-segment severe hypoplasia of the first-order branches. Some of the more peripheral branches also appear small. Note the lack of significant prestenotic and poststenotic dilation. **B:** Long axial oblique view with cranial angulation of the LPA also demonstrates long segment hypoplasia of its mid portion and small peripheral vessels.

Figure 40.20. Lateral projection of a selective right pulmonary artery angiogram in a 23-year-old woman with bilateral pulmonary artery stenosis and supra-valvar aortic stenosis, but without the phenotype for Williams syndrome. Note the “starburst” appearance with origin stenosis of multiple peripheral branches.

Radiation exposure and contrast administration are necessary, but the dose of both is typically lower than needed for angiography to obtain the same information if study protocols are carefully chosen. Exact hemodynamic measurements still require cardiac catheterization. Judicious use of these different modalities should result in increased safety and efficiency for the patient.

Differential Diagnosis

The differential diagnosis of isolated peripheral pulmonary artery stenosis is similar to that of pulmonary valve stenosis. The characteristic systolic murmur that is widely transmitted to the axilla and the back should suggest the diagnosis. Because peripheral pulmonary artery stenosis is commonly associated with other intracardiac and extracardiac malformations, the features of the predominant lesion will determine the clinical picture. A history of maternal rubella, familial congenital heart disease, prolonged neonatal jaundice, and the finding of facies or features suggesting Noonan syndrome or Williams syndrome should suggest the diagnosis of peripheral pulmonary artery stenosis in a patient with a pathologic murmur. Pulmonary artery stenosis should be considered in patients with tetralogy of Fallot and other complex cyanotic congenital cardiac lesions.

Treatment

Mild to moderate isolated unilateral or bilateral peripheral pulmonary artery stenosis usually does not require treatment, but severe cases do require some form of therapy. Prior to 1981, surgical reconstruction was attempted, but the results were suboptimal, prompting the development of catheter therapy. Despite significant improvements in surgical techniques, access to distal vessels remains difficult, and catheter treatment is sometimes the only option.

Balloon Angioplasty

The first use of percutaneous transluminal angioplasty for peripheral pulmonary arterial stenosis was described by Martin et al. (108) in 1980. Subsequently, Lock et al. (109) used the technique in newborn lambs with experimentally produced branch pulmonary arterial stenosis. These investigators demonstrated histologically that successful dilations resulted from intimal and medial tearing of the pulmonary artery wall. These experiments led to the initiation of clinical trials in the early 1980s.

The technique for angioplasty consists of positioning a balloon dilation catheter across the stenotic segment of the pulmonary artery. The balloon diameter usually must be three to four times the narrowest pulmonary artery segment to be effective. Initially, the balloon is inflated to low pressure (1 to 2 atm) while confirming proper position, indicated by a “waist” representing the stenotic segment centered on the balloon. If the diameter of the waist in the balloon is <70% of the balloon nominal diameter at this pressure, the initial dilation should be performed with a different, slightly smaller balloon. Overstretching a tight, noncompliant lesion increases the risk of potentially catastrophic rupture. Under continuous fluoroscopic monitoring, the appropriate balloon is inflated further to higher pressure for a variable period (10 to 60 seconds) until the waist disappears or the maximum pressure is reached. A postdilation angiogram should be performed either just proximal to the dilated area or by advancing an end-hole angiographic catheter over a guidewire left in place across the dilated segment (Fig. 40.21).

Percutaneous balloon angioplasty of peripheral pulmonary artery stenosis has met with a significantly lower success rate than pulmonary valvuloplasty. The criteria used to determine success has been described arbitrarily as an increase of 50% or more in vessel diameter, an increase of more than 20% in flow to the affected lung, or a decrease of more than 20% in systolic right ventricular to aortic pressure ratio (110). The overall acute success rate for patients with varying diagnoses, most commonly tetralogy of Fallot with and without pulmonary atresia, has been reported as 50% to 60% and appears to be similar in the small subset of patients with isolated peripheral pulmonary artery stenosis and intact ventricular septum (110,111). Hosking et al. (111) examined the clinical impact of balloon angioplasty using relatively low-pressure balloons on subsequent management and found that only 35% of patients were favorably influenced by the procedure, with no patient previously considered inoperable becoming operable following angioplasty. A similar study by Zeevi et al. (112) found a 50% rate of favorable clinical impact using more stringent criteria for technical success and high-pressure balloons on some patients. The rate of recurrent stenosis has been 15% to 20% in short to midterm follow-up (110,111); long-term follow-up is unknown.

Because of the disappointing results obtained with low-pressure balloons, high-pressure balloons that can be inflated up to 20 to 25 atm are being used increasingly to dilate pulmonary arteries. The overall acute success rate, defined as 50% or greater increase in vessel diameter or a >20% decrease in right ventricular to aortic pressure ratio, is around 70% to 80%, but still only 50% in patients with isolated peripheral pulmonary artery stenosis (113,114). Limited information is available regarding the frequency of restenosis, but it may be higher than had been previously suspected. Using high-pressure balloons whenever necessary and defining restenosis as >50% decrease in the gain in diameter achieved at the initial successful angioplasty, a restenosis rate of 35% was found at follow-up angiography in a group of 48 patients (115). The only statistically significant variable associated with the occurrence of restenosis was weight at the time of follow-up.

Figure 40.21. Right ventricular angiogram of a 3-year-old boy with truncus arteriosus and right pulmonary artery stenosis before and after balloon angioplasty. A: Stenosis of the right pulmonary artery at its origin and at its midportion is visualized. B: Following angioplasty, the stenotic areas have increased in diameter and the caliber of the vessel is uniformly larger. The systolic pressure gradient from the distal right pulmonary artery to the main pulmonary artery decreased from 36 to 18 mm Hg.

The continued effort to improve on the success rate of balloon angioplasty for resistant pulmonary artery stenosis has recently brought about the use of cutting balloons in this setting (116). These balloons have three or four microsurgical blades with a cutting depth of 0.15 mm mounted longitudinally at 90 degree angles to the balloon. The technique is best suited for small, lobar pulmonary artery branches not amenable to stenting. Vessels resistant to high-pressure balloon angioplasty have been shown to respond to either cutting balloon angioplasty alone or cutting balloon angioplasty followed by high-pressure ballooning (117,118). The longitudinal cuts made by the blades create sites for the tear to propagate when further dilated with a high-pressure balloon. Successful dilation, defined as >50% increase in vessel diameter, has been achieved in 92% of resistant vessels (118). Follow-up data are still very limited, but encouraging (119,120). Much further in the future is the possibility of gene transfer to the pulmonary artery vessel wall via balloon angioplasty techniques, which could result in the expression of angiogenic factors and vessel growth (121).

Significant complications have been reported in 5% to 15% of patients following percutaneous balloon dilation of peripheral pulmonary arterial stenosis (110–113). These complications include exsanguination from a ruptured pulmonary artery either by the dilating balloon or by the guide-wire, hemoptysis, ipsilateral pulmonary edema, obstruction of dilated vessels by intimal flaps, pulmonary artery aneurysms, and clotted iliac veins. Aneurysms typically occur in small distal vessels spanned by the balloon during dilation of a more proximal stenosis. Thus, it is recommended that the balloon be positioned in the largest available distal vessel. A high incidence of aneurysms due to lack of technical control led to abandonment of intraoperative pulmonary artery dilations in many centers (110). Limited midterm angiographic follow-up of these aneurysms showed that they tend to remain unchanged or decrease slightly in size over time, but late enlargement and catastrophic rupture have rarely been seen.

Transient arrhythmias, cyanosis, and hypotension also may occur during pulmonary artery angioplasty.

Special mention should be made of the experience with balloon angioplasty in patients with Williams syndrome (114). Despite a success rate of approximately 50% as defined by a >50% increase vessel diameter, it has been noted that the decrease in right ventricular to aortic pressure ratio is often disappointing. Diffuse hypoplasia of the pulmonary vascular bed, stenoses distal to the dilated segment, and difficulty in dilating central portions of the pulmonary arteries have been implicated. The complication rate is substantially higher than encountered in other subsets of patients with pulmonary artery stenosis, and the incidence of aneurysms has been reported to be as high as 18%. The mortality rate, measured at 7.7% in one series (114), is more than twice that reported in other settings. Interestingly, the cause of death was not associated with pulmonary artery trauma in any of the patients in this study, but rather occurred in patients with significant coronary artery stenosis or ventricular hypertrophy and concomitant subendocardial ischemia with transient hemodynamic perturbations. These findings, coupled with the recognition that spontaneous improvement is often seen in patients with Williams syndrome and pulmonary artery stenosis, have led most investigators to recommend watchful waiting, particularly in young, asymptomatic children, despite significant elevation of the right ventricular pressure. When necessary, a combined approach with distal balloon angioplasty and proximal surgical reconstruction may be the best therapy in this difficult group of patients.

Balloon-Expandable Intravascular Stents

The lack of response to balloon dilation in a substantial number of patients led to the search for more effective transcatheter treatment. The stainless steel balloon-expandable stent developed by Palmaz et al. (122) dramatically improved the effectiveness of balloon angioplasty in a selected group of patients (123,124). Stent placement is accomplished by positioning

Figure 40.22. Right pulmonary artery angiogram of an adult patient with isolated bilateral pulmonary artery stenosis and right heart failure before and after stent placement. **A:** Right axial oblique view demonstrates severe stenosis in the midportion of the right pulmonary artery. **B:** Following stent placement, there is marked improvement in vessel caliber. The proximal LPA was also stented with a similar result. Right ventricular pressure decreased from 55/16 to 42/8 mm Hg with no significant gradients across the stents. Cardiac index increased from 1.9 to 2.7 L/min/m². The patient's symptoms of right heart failure resolved following the procedure.

the stent, mounted on an appropriately sized balloon angioplasty catheter, across the stenotic segment via a long sheath. The sheath then is withdrawn off the stent–balloon angioplasty catheter assembly, and the balloon is inflated to its recommended pressure, expanding the stent and anchoring it in place (Fig. 40.22). Premounted stents may be held securely enough to the balloon to negate the need for advancement through a protective long sheath. Because of the often tortuous course in patients with congenital heart defects, however, dislodgement of the stent can occur, so placement without a long sheath must be done cautiously.

Several investigators reported excellent results acutely as well as in midterm follow-up of stent implantation for pulmonary artery stenosis (123–125), with an increase of more than 100% in stenosis diameter and a >75% reduction in gradient. Most of the patients in these studies had associated congenital heart disease, such as tetralogy of Fallot with and without pulmonary atresia and truncus arteriosus, and a smaller number had isolated congenital pulmonary artery stenosis. Shaffer et al. (124) reported on a group of 15 patients with isolated pulmonary artery stenosis. There was a dramatic immediate decrease in the gradient across the stenotic areas but a less significant decrease in right ventricular pressure than seen in the rest of the group as well as an increase in the right ventricular pressure at midterm follow-up not seen in the other patients. The largest series to date evaluating the immediate and midterm results of stent placement for pulmonary artery stenosis also documents less optimal outcome in this subgroup acutely as well as at a mean follow-up of 5.6 years (125). In a group of 61 patients with isolated congenital pulmonary artery stenosis who underwent placement of 115 stents, the pressure gradient across the stenosis decreased from 50 to 8 mm Hg, on par with the decrease observed in patients with other types of pulmonary artery stenosis. There was also a decrease in the right ventricular to aortic pressure ratio acutely from 0.59 to 0.45. On follow-up, the gradient had increased to 19 mm Hg, similar to the increase observed in the other groups. However, the right

ventricular to aortic pressure ratio had risen to 0.59 (the same ratio as before stenting), while the increase was less significant in other groups. In contrast, follow-up data for the entire cohort of 338 patients, in whom 664 stents were implanted, showed persistent reduction in right ventricular to aortic pressure ratio from 0.66 before stenting, to 0.45 immediately after stenting, and to 0.50 at a mean follow-up of 5.6 year. The rate of restenosis and the incidence of nonphysiologic neointimal proliferation (>1 mm lining on either side of the stent) were only 2% each. The difference in outcome between patients with isolated congenital pulmonary artery stenosis and others, such as patients with tetralogy of Fallot, is felt to be related to the underlying elastin arteriopathy in the former group, rendering the reaction of the vessel wall to the stent less optimal, and resulting in early restenosis (125). These patients are also at higher risk of complications from either balloon angioplasty or stenting of their pulmonary arteries. Of 5 deaths reported by McMahon et al. in their 338 patients, 2 occurred in patients with congenital pulmonary artery stenosis. One patient died of fulminant pulmonary edema after placement of two stents in the left lower lobe, and the other developed massive hemoptysis, a bronchopleural fistula, and died despite lobectomy to control the bleeding.

Complications from stent implantation include incorrect stent positioning or embolization, sometimes requiring surgical removal; thrombosis of the pulmonary artery within the stent (mostly seen in patients with systemic vein to pulmonary artery anastomosis); and all the complications associated with balloon angioplasty alone, including pulmonary edema and pulmonary hemorrhage. Operator experience and technologic advances over the past two decades have been shown to significantly reduce the incidence of complications (125). Lessons learned have led to changes in practice, including avoidance of overdistention and conservative serial dilations in patients with isolated congenital pulmonary artery stenosis, and simultaneous stenting of several branches, or of the right and left pulmonary arteries where applicable, in those with systemic or

suprasystemic right ventricular pressure to avoid flooding a single segment. Technologic advances include shorter stents, improved balloon profiles, central inflation of the stents preventing protrusion of the stent struts into the vessel wall, refinements in techniques to assure stable positioning of the stent over the balloon as it is advanced to the lesion, and more recently, the introduction of premounted stents. These latter stents can be advanced over a wire even without the protection of a long sheath without slippage of the stent off the balloon (126).

At follow-up catheterization, a small and usually hemodynamically insignificant decrease in diameter of the stented vessel has been noted that resulted from neointimal proliferation. McMahon et al. (125) noted an increase in luminal diameter from 5.4 to 11.2 mm immediately after stent placement, and a decrease to 9.3 mm after 5.6 years of mean follow-up. More significant narrowings can develop in areas of diameter mismatch between the stented and nonstented vessel (123) or in between nonoverlapping serial stents. In the majority of cases, the gradient measured on follow-up was due to growth of the vessel wall adjacent to the stent despite the absence of significant restenosis within the stent (125). Stent redilation has been performed safely and effectively in midterm follow-up (127); however, concerns about the unknown long-term effects of stent implantation and about the potential limitations of redilation prompted several investigators to recommend withholding stent placement in very young children (124). In very small patients, stents should be avoided unless the stent utilized has the capacity to later be enlarged to adult diameter. For older children and adult patients, in whom stents can be dilated at the initial or subsequent catheterizations to the required adult size of the vessel, stent placement has become the preferred therapy for refractory branch pulmonary stenosis. Future technologic advances such as biodegradable stent designs may further expand the indications for pulmonary artery stent implantation to all age groups (128).

Surgery

Early attempts to relieve pulmonary artery stenosis were confined to the main pulmonary artery or origin of the branch pulmonary arteries with varying success. Multiple peripheral stenoses were first tackled by McGoon et al. (129) using an azygous vein graft to patch over the incised stenotic segments. Further surgical experience with pulmonary artery reconstruction was gained primarily in patients with tetralogy of Fallot with pulmonary atresia and aortopulmonary collateral arteries. When native arterioplasty is not sufficient, stenotic segments are enlarged, preferably with autologous pericardium and occasionally with azygous vein grafts. Isolated congenital peripheral pulmonary artery stenosis, often accompanied by long-segment hypoplasia, is difficult to treat successfully with either balloon angioplasty or surgery. In our institution, various techniques are used to deal with this lesion, including excision of stenotic segments, augmentation of stenotic branching points using cutback angioplasty, and use of an autologous pericardial roll to restore arterial continuity when direct anastomosis is not possible. At least one patient with severe bilateral branch pulmonary artery stenosis was treated surgically with near normalization of right ventricular pressure (130) (Fig. 40.23). A combined approach, with surgical reconstruction followed by transcatheter pulmonary artery intervention, is often the best form of treatment.

Course and Prognosis

Routine prophylaxis against endocarditis in patients with peripheral pulmonary stenosis is not recommended. Most patients with mild or moderate stenosis remain stable, and pressure gradients recorded early in life often decrease with growth.

Figure 40.23. Pulmonary artery angiogram of the same patient depicted in Figure 40.19 following surgical reconstruction. The right ventricular pressure decreased from 102/6 to 40/5 mm Hg.

This is particularly true in patients with associated syndromes such as Williams, Noonan, or congenital rubella; however, multiple peripheral pulmonary stenosis of severe degree may be progressive (102,131), and the prognosis is poor unless angioplasty, stent placement, or surgery is successful. Complications include right ventricular failure, pulmonary artery thrombosis, and poststenotic aneurysmal dilation with pulmonary artery hemorrhage. Death in childhood has been reported (131).

PULMONARY ARTERY STENOSIS IN YOUNG ADULTS

Isolated peripheral pulmonary artery stenosis is rarely seen in adult patients, and often is misdiagnosed as chronic pulmonary thromboembolic disease (132). These patients typically present with exertional dyspnea and fatigue, and symptomatic improvement has been seen following balloon angioplasty. Systemic vasculitis with pulmonary arterial involvement should be excluded. The presence of murmurs consistent with pulmonary artery stenosis in many of these patients in childhood or adolescence suggests a congenital etiology with slow progression. Inadequately repaired pulmonary artery branch stenosis may be seen in patients who underwent childhood repairs of lesions such as tetralogy of Fallot, truncus arteriosus, or transposition of the great arteries (if arterial switch procedure was utilized). Abnormal distribution of pulmonary blood flow has been associated with reduced exercise capacity (133).

Pulmonary Atresia and Intact Ventricular Septum

David G. Nykanen

A discussion of pulmonary atresia (PA) and intact ventricular septum (IVS) would be incomplete without acknowledging the legacy of Robert M. Freedom. As a clinical cardiac morphologist, his monograph described the diversity of this malformation, emphasizing the complexity of a disorder that appears so simple on the surface (1). His understanding of the nature of this condition has endured the test of time and continues to influence our treatment strategies today. To those who were fortunate to know him, he was a passionate, tireless teacher dedicated to the concept that the practice of knowledge-based medicine incorporates observations gained from both an understanding of the literature and the recognition of the value of cumulative experience. Scholars of pediatric cardiology will continue to identify Robert Freedom's contributions to our understanding of PA and IVS for decades to come. It is appropriate that many of his insights continue to be reflected in the pages that follow.

PA and IVS was first described in 1783 by Hunter (2) and then revisited 86 years later by Peacock in 1869 (3). While its name focuses primarily on membranous or muscular atresia of the right ventricular outflow tract, this disorder is characterized by striking heterogeneity of the right ventricle, its inlet, and its functional size. Furthermore, many of these patients have connections between the right ventricle and subepicardial coronary arteries and a predisposition for an unusual coronary circulation. These connections were originally a pathologic curiosity; however, management can be dictated by their nature. Prognosis appears to relate to the nature of the coronary circulation in the right ventricle at high pressure or, alternatively, the presence of severe tricuspid regurgitation in the setting of a low-pressure right ventricle (4–6). It is truly a complex, diverse disorder that challenges surgical and catheter-based interventional strategies. Current interventional algorithms range from achieving a biventricular circulation and variations of the cavopulmonary circulation (Fontan operation or 1.5-ventricle repair) to cardiac transplantation.

EPIDEMIOLOGY

Data obtained from the New England Regional Infant Cardiac Program identified 75 patients with this disorder, accounting for 3.1% of all infants enrolled in the study. The Baltimore-Washington Infant Study defined the prevalence for this disorder as 0.083 per 1,000 live births (7). Despite being uncommon, when integrated into the overall statistics of congenital heart disease, PA/IVS is one of the more common cardiac etiologies of cyanotic congenital heart disease in the neonate, along with transposition of the great arteries and PA with ventricular septal defect. A published study from the United Kingdom and Eire defined the incidence of PA and IVS to be 4.1 per 100,000 live births (8). Overall, by the best estimates, PA and IVS occurs at a rate of 0.6/10,000 live births. However, if one includes

pregnancies that are aborted spontaneously or electively after 20 weeks' gestational age with live births, the rate has been reported as much as 10 times higher at 0.6/1,000.

Fetal echocardiography provides a unique window to study the later phases of the fetal heart development recognizing that cardiac organogenesis is complete by about 8 weeks' gestation. There is increasing evidence that fetuses with severe tricuspid regurgitation may not fare well. Such fetuses are known to develop right-sided heart failure with pleural and pericardial effusions, ascites, pulmonary hypoplasia, and fetal death. Thus, fetal loss might be anticipated in a specific subset of patients with PA, IVS, extremely severe tricuspid regurgitation, and a low-pressure right ventricle. The data collected from the United Kingdom and Eire also showed that termination of pregnancy once this diagnosis was established led to an important reduction in live-born incidence in mainland Britain (8). Prenatal echocardiography is becoming an important predictor of postnatal management of this patient population and likely will grow to include strategic application of in utero intervention (9–13).

DEFINITION

The usual form of PA and IVS occurs in a left-sided heart with normal atrial relations, concordant atrioventricular connections, and concordant ventriculoarterial connections. As its name implies, the right ventricular outflow tract is imperforate and this can be either membranous or represented by a longer segment of muscular atresia. The ventricular septum functionally is intact. A patent arterial duct usually mediates pulmonary blood flow. Very rarely, multiple direct aortopulmonary collaterals originating from the descending thoracic aorta are the sole sources of pulmonary arterial supply. Nonconfluent pulmonary arteries, each supplied by a patent arterial duct, also have been recognized, but this situation also is uncommon (14).

MORPHOGENESIS

Kutsche and Van Mierop (15) suggested that PA with ventricular septal defect occurs earlier in cardiac morphogenesis than PA and IVS. This conclusion is based on an analysis of a number of morphologic factors, including the diameter of the pulmonary trunk, the morphology of the pulmonary valve, and the morphology and topography of the ductus arteriosus. They postulated that PA and ventricular septal defect occur early in cardiac morphogenesis at or shortly after partitioning of the truncoconal part of the heart but before closure of the ventricular septum. Conversely, they suggest that PA and IVS probably occur after cardiac septation. For some forms of hearts with PA and IVS, it is possible that their conclusions about the timing of maturational arrest are correct, specifically

for patients with PA and IVS, a nearly normal-sized right ventricle, and an imperforate “tricuspid” pulmonary valve whose commissures are completely fused.

Embryologically, this defect must occur after ventricular septation is complete as the septum is, by definition, intact. An abnormality of intracardiac blood flow may result in atresia of the valve, thus further altering blood flow and ventricular growth. Animal experiments have demonstrated that reduced flow to a heart structure, even late in gestation, can have devastating effects on the development of associated structures (16,17). The concept is further evidenced by current (as yet unproven) experimental fetal interventional strategies for treatment during pregnancies that are aimed at restoring normal flow patterns in an effort to promote growth or prevent regression of cardiac chamber size. While human fetuses with PA and IVS demonstrate abnormalities in intracardiac blood flow, the specific etiology of the blood flow abnormality remains unknown.

The tricuspid valve in this condition usually is abnormal. This makes intuitive sense as any blood entering the fetal right ventricle has no egress; hence it must regurgitate. The annulus may become hypoplastic, the leaflets of the valve abnormal, and the chords supporting the valve malformed or damaged due to the high pressures in the ventricle created by the lack of an egress of blood from the right heart. Once the valve begins to leak, it is further altered structurally by turbulent flow.

Another very important prognostic feature concerns the presence or absence of ventriculocoronary connections and coronary artery abnormalities. Conceptually, if the pressure is very high in the right ventricle and the blood has nowhere to go, the ventricle can develop these connections to partially decompress in fetal life. Once these connections have formed, they have not been demonstrated to disappear. Shear forces created by blood flowing at high pressure within these connections can result in progressive stenosis and interruption of the coronary arteries that effectively renders the circulation of major portions of heart muscle dependent on flow from the right ventricle. This is recognized after birth as a “right ventricular-dependent coronary circulation” and in its worst form is an absolute contraindication to decompressing the right ventricle by surgery or transcatheter methods.

The pulmonary valve is derived from endocardial tissue within the conotruncus. Abnormalities in morphology of the pulmonary valve can result from failure of normal development of the valve itself. In this setting, the valve consists of the usual three leaflets, but they have markedly thickened abnormal cusps of myxomatous tissue. It often is accompanied by abnormalities of the valve annulus and the sinotubular junction. These types of valve abnormalities have been linked to genetic conditions such as Noonan syndrome and Williams syndrome as well as environmental exposures such as rubella. Here the problem clearly occurs early as a result of abnormal formation of the valve itself. This is in contrast to the valve that has been subject to abnormalities of flow after it has developed where the leaflets are thickened and fused together with a near-normal-appearing sinotubular junction.

PATHOLOGY AND PHYSIOLOGY

Gross External Inspection

The heart may be only mildly enlarged, or it may be massively enlarged, with a hugely dilated right atrium occupying much of the right hemithorax. In this latter situation, the lungs may be compressed by the enlarged heart and may exhibit a varying degree of hypoplasia. When the heart is only mildly enlarged, the course of the anterior descending coronary artery in the anterior interventricular sulcus outlines a smaller than normal

Figure 41.1. Intraoperative photograph of the epicardial surface of the heart of a patient with pulmonary atresia and intact ventricular septum with right ventricle to coronary connections. The coronary arteries are dilated (arrows) with aneurysmal dilation (asterisk).

right ventricle. The right atrium usually is somewhat enlarged, accounting for the cardiomegaly. The right ventricle may be profoundly thinned, and this may be apparent even with the heart in situ.

From external inspection of the heart, there may be obvious clues that there are significant abnormalities of the coronary artery circulation. The coronary arteries may be obviously thickened and nodular, and rarely the coronary arteries may be seen connecting with the pulmonary trunk. Severe abnormalities may be readily apparent with epicardial aneurysmal dilation (Fig. 41.1). So-called dimples may be observed on the epicardial surface of the heart, usually, but not exclusively, in association with the subepicardial coronary arteries. Such dimples may be considered the external stigmata of ventriculocoronary connections and may indicate the site of such connections.

Nature of the Pulmonary Atresia

Braunlin et al. (18) documented the morphologic bases for PA in this disorder, correlating the type of imperforate pulmonary valve with the character of the right ventricle and its infundibulum. In patients with a well-formed infundibulum, the imperforate pulmonary valve exhibits three semilunar cusps with complete fusion of the commissures (Fig. 41.2). The pulmonary valve is primitive in patients with a diminutive right ventricle and a severely narrowed or atretic infundibulum. The muscular nature of the infundibulum has received both morphologic and clinical and angiocardiographic attention, and the nature of those right ventricular muscle bundles contributing to the infundibular atresia has been described.

Great Veins, Atrial Septum, Coronary Sinus, and Venous Valves

A peculiar relationship exists between persistent right venous valve, ventriculocoronary connections, and PA/IVS. It would be too simplistic, indeed incorrect, to speculate that a persistent venous valve is causal to right-sided heart hypoplasia. The

Figure 41.2. Appearance of pulmonary valve in a patient with pulmonary atresia and intact ventricular septum. The valve leaflets are reasonably well identified.

coronary sinus usually terminates in the right atrium. Stenosis and atresia of the coronary sinus ostium have been observed, with decompression through an unroofed coronary sinus–left atrium fenestration.

Because of the obligatory right-to-left shunt at atrial level, with rare exception, there is either a patent foramen ovale or true secundum atrial septal defect. Premature closure of the foramen has been observed in this disorder, usually with fetal death. Rarely, if the interatrial septum is intact or nearly so, alternative pathways for systemic venous return have been recognized, including coronary sinus–left atrial fenestration. The septum primum may assume aneurysmal proportions in patients with a restrictive atrial septal defect, and its herniation through or obstruction of left ventricular inflow has been observed.

Tricuspid Valve

The tricuspid valve rarely is normal in patients with PA and IVS. This atrioventricular valve demonstrates the continuum of abnormalities and a functional impact that ranges from extreme stenosis to profound regurgitation (19) (Fig. 41.3). The stenotic valve can demonstrate a hypoplastic obstructive annulus that may be muscularized with a very abnormal valve apparatus consisting of a thickened free valve margin, shortened dysplastic chordae, and papillary muscle abnormalities. The severely regurgitant valve can be characterized by a dilated annulus. In this situation, the valve exhibits both profound displacement similar to the severest form of Ebstein anomaly and dysplasia. In some severely regurgitant valves, the valve is not displaced but it is extremely dysplastic. Rarely, the valve orifice may be virtually unguarded, a situation similar to profound Ebstein anomaly (20). The most severely stenotic and obstructive tricuspid valve is observed in patients with the most hypoplastic of right ventricles. Conversely, patients with a large right ventricle usually have severe tricuspid regurgitation with a valve exhibiting features of Ebstein anomaly and dysplasia. This latter malformation represents a major management challenge with a poor overall prognosis.

Right Ventricle

Clinicians and pathologists have attempted to characterize the size of the right ventricle in this disorder for decades.

Methodologies have included angiocardiographic volumetric analysis, a variety of measurements of the inlet/outlet axis, and the convention advocated by the Congenital Heart Surgeons Study (CHSS), that is, the use of the so-called tricuspid diameter Z value (5). This is the diameter of the tricuspid valve normalized to body surface area and was based on an early pathologic study of the normal quantitative anatomy. Data from the CHSS showed that the Z value of the tricuspid valve was correlated with the size of the right ventricular cavity ($r = 0.68$, $p < 0.0001$), and this relationship has been confirmed in more recent studies as well (21). This continues to be referenced to the present day.

Others have advocated a semimorphologic approach to the right ventricle. Although there is no consensus as to whether the morphologically right ventricle is embryologically a bipartite or tripartite structure, there are examples of congenitally malformed hearts that may support the view of the right ventricle as a tripartite structure. Taking this latter approach, the normal right ventricle can be considered to be composed of confluent inlet, apical trabecular, and outlet components. This approach has been used widely in the categorization of patients with PA and IVS. Thus, some patients have PA and IVS, wherein the right ventricle is particularly well formed and all three components are well represented. In others, the right ventricle is extremely underdeveloped and seemingly limited to an inlet only (22) (Figs. 41.3C–E and 41.4). Attempts to characterize the size of the right ventricle are plagued by difficulty in assessing the contribution of muscular hypertrophy of the apical and outlet myocardium (23). This has tremendous impact on clinical management as it appears that relief of outflow tract obstruction with associated pulmonary insufficiency may result in remodeling with regression of hypertrophy that can result in real or perceived growth of the right ventricle (23–30).

Left Atrium, Left Ventricle, and Aortic Valve

The left atrium usually receives the pulmonary veins in a normal fashion, although one or more pulmonary veins may connect anomalously to the systemic circulation. The left ventricle may exhibit variable degrees of hypertrophy, especially in patients who survive past infancy. Some years ago, attention was given to a convexity of the outlet portion of the interventricular septum that occurred in those patients with small and extremely hypertensive right ventricles (Fig. 41.5). In this setting, severe left ventricular outflow tract obstruction resulting in death occurring after surgical creation of a cavopulmonary connection has been observed when there is an unfavorable change in the ratio between left ventricular mass and end-diastolic volume (31,32). Aortic valve stenosis has been described in patients with PA and IVS, including the neonate with critical aortic stenosis and the somewhat older child with severe aortic valve stenosis (33). With rare exceptions, the aortic arch is left sided.

Pulmonary Circulation

Confluent pulmonary arteries usually receive flow from a left-sided ductus arteriosus. Rarely, nonconfluent pulmonary arteries are supported by bilateral ductus arteriosus or aortopulmonary collaterals (34). A main pulmonary trunk almost always is present. Unlike the patient with PA *with* ventricular septal defect, the caliber of the pulmonary arteries in patients with PA and *intact* ventricular septum is rarely a major determinant of outcome. This may be in part mediated by the observation that the arterial duct tends to close earlier in patients with PA and intact septum than it does in patients with PA and ventricular septal defect (35). More recently, transcatheter

Figure 41.3. means of maintaining pulmonary blood flow such as stenting of the arterial duct have necessitated increased awareness of the assessment of the neonatal anatomic details of the pulmonary artery at the insertion of the patent ductus arteriosus (36–39).

Myocardial Abnormalities

The myocardium of patients with PA and IVS can demonstrate a wide range of abnormalities. Ischemia, fibrosis, infarction,

and myocardial rupture have been observed in these patients (40–45) (Fig. 41.6). Other abnormalities include myocardial disarray, the appearance of so-called spongy myocardium, and ventricular endocardial fibroelastosis. In this regard, an inverse relationship exists between ventricular endocardial fibroelastosis and extensive ventriculocoronary communications. Perhaps this observation is fundamental to the frequent finding of ventriculocoronary connections in PA and IVS: dense, “sugar-coated” right ventricular endocardial sclerosis is uncommon. Conversely, dense, sugar-coated left ventricular

Figure 41.4. Severe right ventricular underdevelopment in a patient with pulmonary atresia and intact ventricular septum. Severely hypoplastic right ventricle with free-wall and septal hypertrophy (see also Fig. 41.2C–E).

endocardial sclerosis is common in patients with a hypoplastic left heart syndrome; but a perforate mitral valve, and thus ventriculocoronary connections, is uncommon. The right ventricular myocardium may be particularly thinned in babies with severe tricuspid regurgitation.

Coronary Arteries

It is important to gain an understanding of the status of the coronary circulation in patients with PA and IVS prior to proceeding with an interventional algorithm because myocardial ischemia may be related to the presence and extent of these ventriculocoronary connections. An extensive literature has documented the vast array of changes in the coronary arteries among some patients with PA and IVS (46–50). Several articles have characterized the histopathologic

Figure 41.6. Myocardial abnormalities seen in some patients with pulmonary atresia and intact ventricular septum. A: Acute myocardial infarction with rich inflammatory infiltrate and loss of cellular integrity. B: So-called spongy myocardium with endothelial-lined vascular lakes.

alterations of the involved coronary arteries. This process is not characterized by inflammation, as once thought, but more appropriately as myointimal hyperplasia with a rich background of glycosaminoglycans. There is a wide spectrum of histopathologic lesions of both the extramural and intramural coronary arteries. These lesions range from mild degrees of intimal and medial thickening in which a continuous internal elastic lamina and normal lumen is present to a loss of normal arterial wall morphology with replacement of the arterial wall by fibrocellular tissue containing irregular, unorganized elastin strands and severe stenosis or obliteration of the arterial lumen. Some have designated these changes as fibroelastosis of the coronary arteries, but emphasis would be more appropriately focused on myointimal hyperplasia. Staining for glycosaminoglycans shows the prominence of ground substance formation by the activated smooth-muscle cells rather than the reduplicated elastica and collagen characteristic of fibroelastosis (Fig. 41.7). This pathologic process leads to a profound distortion of the normal architecture, eventuating in endothelial irregularity, stenosis, or interruption. Such coronary arterial involvement occurs only in patients with ventriculocoronary connections and, by inference, with a hypertensive right ventricle. The pathogenesis of these arterial lesions likely is predicated on the repeated and sustained injury to the coronary arterial intima from high-pressure right ventricular systolic turbulent blood flow mediated by the presence of the ventriculocoronary connections. Intramural or extramural coronary arteries remote

Figure 41.5. Note septal convexity (*asterisk*) in a patient with pulmonary atresia and intact ventricular septum. It has the potential for promoting left ventricular outflow tract obstruction after Fontan repair.

Figure 41.7. from the ventriculocoronary connections do not demonstrate these arterial lesions, nor do hearts not exhibiting ventriculocoronary connections. These lesions have been found in fetal hearts with PA and IVS and in hearts of the immediate newborn. Ventriculocoronary connections do not occur in thin-walled, low-pressure right ventricles.

The coronary abnormalities in patients with PA and IVS embrace the same spectrum of abnormalities as those seen in patients with otherwise normal hearts, including abnormalities of origin, epicardial course, and number. A single coronary artery may originate from the aorta or, rarely, from the pulmonary trunk. Many congenital and acquired conditions of the coronary circulation are specific to PA and IVS and impact surgical management. These conditions include an absence of a proximal aortocoronary connection between one or both coronary arteries, coronary arterial stenosis or interruption, or a so-called coronary–cameral fistula with a major fistula between the right or left coronary artery and the right ventricle. Peculiar arterial connections such as those from the descending thoracic aorta or the gastric artery to the coronary circulation very rarely have been described.

Right Ventricular–Dependent Coronary Artery Circulation

Intrinsic to awareness of ventriculocoronary connections in this disorder and their impact on the myocardium is the concept of a right ventricular–dependent coronary artery

TABLE 41.1 **A Right Ventricular–Dependent Coronary Circulation**

Coronary artery abnormalities requiring right ventricular blood flow:

- Absent aortocoronary connections
- Coronary artery interruption or stenosis
- Profound coronary–cameral steal or fistula

circulation (Table 41.1). In the normal circulation, it is in large part the aortic diastolic pressure that is the driving pressure for coronary blood flow. Factors that reduce aortic diastolic pressure or shorten diastole will compromise coronary blood flow. The presence of ventriculocoronary artery connections may promote coronary artery stenosis and interruption, and aortic diastolic pressure may not be sufficient to drive coronary blood flow when obstructive lesions are present within the coronary circulation. It is important to remember that these infants are hemodynamically fragile, tachycardic, and often receiving prostaglandin or palliated with a systemic-to-pulmonary artery shunt to augment pulmonary blood flow. Notably these therapeutic maneuvers also will reduce aortic diastolic pressure. Therefore, retrograde coronary blood flow from the hypertensive right ventricle occurring during systole and mediated by the ventriculocoronary connections may be necessary to sustain adequate myocardial perfusion. In a coronary circulation that is wholly or in part right ventricular dependent, it is the blood that gets into the right ventricle at systemic or above-systemic right ventricular systolic pressure that supplies the dependent myocardium in a retrograde fashion. Unfortunately, this process can lead to further coronary arterial distortion. The management corollary to this is clear: interference with blood flow into the right ventricle or reduction of right ventricular systolic pressure in situations in which the coronary circulation is right ventricular dependent may result in myocardial ischemia, infarction, and death.

There is unequivocally a predisposition to ventriculocoronary connections among patients who have the smallest right ventricles. Thus, it is unlikely but not impossible to define such abnormal communications in patients with a normal-sized right ventricle or with a nearly normal right ventricle (51). It is much more likely to observe ventriculocoronary communications in patients whose ventricles have been categorized as unipartite or bipartite. Using the convention of the tricuspid Z value, data from the CHSS demonstrated a positive correlation with ventriculocoronary connections: a negative tricuspid Z value correlates with the presence of ventriculocoronary connections. Data from this study support the observation that the smallest tricuspid valve (i.e., the most negative Z value) is observed in patients with the smallest right ventricle (5). Data provided by the CHSS indicated that, of the 145 patients for whom this information was available, ventriculocoronary connections were observed in 45%. In 9% of the 145 patients, the coronary circulation was considered wholly right ventricular dependent. Ventriculocoronary connections may involute after successful right ventricular decompression (whether by pulmonary valvotomy or tricuspid valve excision or avulsion). Such involution has been demonstrated in the newborn and in the older patient. With reduction in right ventricular pressure, there is always the possibility that flow from the coronary artery to the right ventricle might occur or become exaggerated, and this phenomenon has been recognized.

Perhaps of more concern is determination of the timing of the occurrence of coronary arterial obstructive lesions, coronary artery stenosis, or interruption. Such coronary arterial obstructive lesions can occur in fetal tissues, and these lesions have been identified clinically by both angiography and histopathology in hearts from patients who die in the first few hours and days after birth. Thus, such changes should not be interpreted as a later, acquired postnatal phenomenon (47). Obviously, some changes may be acquired late, but clearly obstructive coronary arterial lesions may be identified in the immediate newborn.

CLINICAL FEATURES

Physical Examination

Newborns with PA and IVS become cyanotic and hypoxemic coincident with functional and anatomic closure of the patent arterial duct. In the rare patient in whom the interatrial communication is truly restrictive, the cardiac output may be affected as well by restricting the obligatory right-to-left shunt.

There is no known sex predilection, and there is no identified genetic predisposition, although familial cases have been described as well as an occurrence in monozygotic twins (52). It has been assigned to a single gene theory in at least one instance (53). Infants typically are born at term. Cyanosis usually is apparent within hours of birth and is progressive. Dyspnea is not conspicuous without significant acidosis, reduced cardiac output, or pulmonary hypoplasia, but tachypnea may be prominent.

In the absence of profound cardiac enlargement, the left precordium will not bulge. The left ventricle may be enlarged, and at the apex, its impulse may be forceful. The first and second heart sounds are single. A pansystolic murmur often is audible at the left lower sternal border, consistent with tricuspid regurgitation. In infants with severe tricuspid regurgitation, the murmur of tricuspid regurgitation is conspicuous, sometimes associated with a thrill, and a tricuspid diastolic rumble may be audible. A murmur of the arterial duct may be distinguished in the second and third left intercostal space, especially after prostaglandin has been administered to promote ductal patency. Unless the atrial septum is profoundly restrictive, affecting cardiac output, the caliber of the arterial pulses is normal. The liver is not particularly enlarged unless there is severe tricuspid insufficiency or a restrictive foramen ovale.

The most striking and consistent finding before prostaglandins are administered is hypoxemia refractory to increased inspired oxygen concentration and a mild degree of hypocarbia, reflecting the tachypnea. Significant metabolic acidosis usually indicates progressive hypoxic cellular damage signifying imminent death in the absence of intervention.

Radiographic Features

The chest radiograph may demonstrate a heart that is only mildly enlarged or one that fills the entire chest cavity. In the former, the pulmonary vascular markings are reduced, which may be confirmed on the lateral radiograph, where hilar pulmonary arterial markings are sparse. In the latter situation, with massive cardiomegaly, it may be difficult to define enough pulmonary parenchyma to evaluate the lung markings. The differential radiographic diagnosis of extreme cardiomegaly in the newborn includes the conditions shown in Table 41.2.

Intrapericardial teratoma

AV, atrioventricular; VA, ventriculoarterial.

Electrocardiographic Features

The classic electrocardiogram shows normal sinus rhythm, a frontal QRS axis of +30 to +90, a paucity of right ventricular forces, left ventricular dominance or left ventricular hypertrophy, and right atrial enlargement. There frequently are abnormalities of the ST-T segments, consistent with some degree of subendocardial ischemia. The differential diagnosis based on the electrocardiogram is shown in Table 41.3. The differential diagnosis of a cyanotic baby with a soft systolic murmur, mild cardiac enlargement, and oligemic lungs is fairly extensive (Table 41.4).

Echocardiographic Features

Although echocardiography has been advocated as the imaging modality for the diagnosis and treatment of many forms of neonatal congenital heart disease, both echocardiography and angiocardiology are often required for a complete evaluation of this disorder. It is not that echocardiographer cannot make the diagnosis of PA and IVS. Rather, important consideration in the treatment algorithm of neonates with PA and IVS is given to the presence of right ventricular to coronary artery connections and a right ventricular-dependent coronary circulation, especially if one is considering decompressing the right ventricle by creating continuity between the right ventricle and the pulmonary circulation. Identification of the extent of ventriculocoronary connections can be difficult by echocardiography. Echocardiographic imaging has not allowed one to identify reliably coronary arterial stenosis or interruption in neonates. As a result of these limitations, angiocardiology can be very important in infants with severe hypoplasia of the right ventricle, in whom a high incidence of ventriculocoronary artery connections is anticipated. Because ventriculocoronary connections have been observed in the

patient even with a normal-sized right ventricle, all patients should undergo angiocardigraphic imaging prior to ventricular decompression. This is not intended to underestimate the importance of echocardiography as a primary diagnostic tool in those neonates with PA and IVS. Indeed, the initial therapeutic plan often is dictated by echocardiographic findings (Figs. 41.8–41.13).

It is important to ascertain the functional status of the interatrial septum as the neonate relies on obligatory right-to-left shunting to maintain cardiac output. The interatrial communication can be assessed readily by the subcostal approach with a combination of imaging and Doppler interrogation. The atrial septum rarely may assume aneurysmal proportions, with septum primum herniating through the mitral valve. The size and morphology of the tricuspid valve must be assessed. It may be difficult to detect forward flow across an extremely stenotic, obstructive tricuspid valve and patency may be determined best by the identifying tricuspid regurgitation. In the absence of Doppler detection of tricuspid regurgitation, the question of patency cannot always be resolved. The right ventricular size, which usually corresponds to the dimension of the tricuspid annulus, can be imaged by a combination of subcostal and precordial views. Absolute volume measurements are of limited value at the present time, although in the future,

three-dimensional echocardiography may provide further insights. Hypoplasia, if present, may involve all components of the right ventricle. Although the noninvasive identification of pulmonary infundibular and valve atresia is recognized readily (Figs. 41.9 and 41.11), it may be difficult to distinguish isolated valve atresia from extremely severe stenosis. Even with the application of Doppler echocardiography, this issue remains a problem because ductal flow potentially can mask a small jet of forward flow.

It is important to distinguish anatomic from functional PA. In the former, the pulmonary valve is anatomically imperforate, whereas in the latter, the lack of forward flow is due to high pulmonary artery pressure with poor right ventricular function or very severe tricuspid insufficiency. In general, the pulmonary valve is morphologically normal but functionally closed. As discussed previously, it also is possible to have anatomic valve atresia with extreme tricuspid regurgitation and a low right ventricular pressure, hence the importance of differentiating the two conditions. With the use of Doppler echocardiography, it is possible to do this by detecting systolic regurgitation of the pulmonary valve, which is caused by a jetting effect of the patent ductus arteriosus against the valve (Fig. 41.12). This is not observed in patients with anatomic pulmonary valve atresia. Another technique is through the use of Doppler echocardiography during positive pressure ventilation, which transiently results in opening of the pulmonary valve and forward Doppler flow. Finally, an attempt to document coronary artery connections from the right ventricle should be made, recognizing that this can be difficult (Fig. 41.13) (54).

Cardiac Catheterization

If one is considering decompression of the right ventricle, then a full hemodynamic and angiocardigraphic investigation is required for the interventional management of the neonate with PA and IVS. Although one can recognize echocardiographically the presence of large ventriculocoronary connections or fistulae, this technique does not allow for the recognition of coronary artery stenosis or interruption, both of which have been documented in the newborn. Significant coronary artery abnormalities with a right ventricle dependence for myocardial flow has been predicted by an evaluation of the size of the tricuspid valve relative to the patient size with a Z-score of < -2.5 predicting clinically important

abnormalities (51). Furthermore, using echocardiography, it may be difficult to document without any doubt those patients with tenuous proximal aortocoronary connections (55).

The level of systemic arterial oxygen saturation data reflects the magnitude of pulmonary blood flow. Before the era of routine administration of prostaglandin, these infants became progressively hypoxemic coincident with functional and anatomic closure of the arterial duct. All these infants experience an obligatory right-to-left shunt at the atrial level. Unless there is pulmonary disease, the pulmonary venous saturation is normal, or nearly so. The administration of prostaglandin, by virtue of its action on the arterial duct and the pulmonary vascular resistance, augments pulmonary blood flow, and thus arterial saturation increases.

The hemodynamic evaluation of the patient with the hypertensive right ventricle establishes right ventricular pressure at or above systemic levels. When dealing with the patient with massive cardiac enlargement, right ventricular pressure may be substantially less than systemic. These patients raise the possibility that the obstruction to pulmonary blood flow reflects functional rather than anatomic PA.

Figure 41.10. The topography of the interventricular septum bowing into the left ventricular outflow tract. **Upper panel:** A precordial long-axis view. **Lower panel:** Short-axis view. AO, aorta; LA, left atrium; LV, left ventricle; RV, right ventricle (see also Fig. 41.4).

In the presence of nonrestrictive interatrial communication, the atrial mean pressures equalize, although there is often a small “a” wave gradient from the right to the left atrium. If true restriction to atrial flow is demonstrated then it is important to consider a balloon atrial septostomy at catheterization to avoid a low cardiac output syndrome, especially if decompression of the right ventricle is not to be included in the therapeutic track. The right ventricle is at systemic levels of pressure or higher, and the end-diastolic pressure may be abnormally high, consistent with a noncompliant ventricular chamber. Alternatively the right-to-left ventricular pressure ratio may be <1 . The finding of a subsystemic right ventricular pressure is consistent with a globally disadvantaged right ventricle. The right ventricle is usually thinned, and severe tricuspid regurgitation often is present. The functional disturbance of severe tricuspid regurgitation correlates with an Ebstein-like abnormality of the tricuspid valve or severe tricuspid valve dysplasia. Rarely, the tricuspid valve may be unguarded, or nearly so.

Angiocardiography remains an important imaging modality in patients with PA and IVS (Figs. 41.14–41.18). Although much of the intracardiac anatomy can be determined from a

Figure 41.11. The pulmonary outflow tract in this patient with valvar atresia is imaged in the precordial short-axis view with slight clockwise rotation. **Upper panel:** Anatomic pulmonary “annulus”. **Lower Panel:** The possibility of pulmonary insufficiency (red flow) raises the possibility that the valve is severely stenotic and not atretic. systematic approach to echocardiography, right ventricular angiocardiography provides information about the form and function of the tricuspid valve, the size of the morphologically right ventricle, the extent of the apical trabecular zone, and the dimensions and degree of expansion of the infundibulum of the right ventricle. Most importantly, right ventricular angiography will define the presence or absence of ventriculocoronary connections. Selective injection of the right ventricular outflow tract can differentiate severe stenosis of the pulmonary valve from membranous atresia (56). Selective left ventricular angiocardiography provides information about the form and function of the left ventricle and aortic valve, and this certainly complements echocardiographic imaging. Aortography in the neonate defines the laterality of the aortic arch, the caliber of the subclavian arteries, the site of insertion of the arterial duct, the caliber of the pulmonary arteries, and coarctation of the pulmonary artery at the insertion of the arterial duct that may preclude treatment with a stent to permanently maintain its patency or require a surgical patch at the time of placing a

systemic-to-pulmonary artery shunt. A balloon occlusion technique performed in the newborn's ascending aorta will allow imaging of the coronary arteries, their origin, epicardial distribution, and caliber changes indicative of stenosis or interruption. In some patients, including newborns, selective coronary arteriography may be necessary to characterize fully the coronary arterial involvement. When right ventricular angiography does not demonstrate ventriculocoronary connections, one can be reasonably certain that coronary arterial stenosis or interruption or major fistulae with coronary–cameral flow will not be evident. In some patients with ventriculocoronary connections, a balloon catheter inflated in the right ventricle or catheter-induced tricuspid insufficiency with concurrent observation of the simultaneous electrocardiographic tracing may unmask a right ventricular–dependent coronary circulation.

The angiocardiographic investigation of the patient with the hypertensive right ventricle requires right ventricular angiocardiography in frontal and lateral projections (Figs. 41.14 and 41.16). Further information can be obtained with angulated views of the right ventricular angiogram in the setting of ventriculocoronary communications (Fig. 41.17). It remains to be seen whether advanced imaging techniques such as three-dimensional rotational angiography will augment the evaluation of coronary pathology in this condition (Fig. 41.19).

TREATMENT

Medical

Immediate attention must be paid to maintaining ductal patency, which can be accomplished by the systemic administration of prostaglandin. The reported surgical survival of 27% prior to the availability of prostaglandins was poor (57). Rarely an urgent balloon atrial septostomy may be required for a restrictive septum as pulmonary flow improves and should be considered in any neonate that demonstrates persistent low cardiac output with the usual therapeutic maneuvers. For the premature infant or the extremely small-for-gestational-age infant, a prolonged course of an E-type prostaglandin may be necessary before surgery is undertaken, although this is unusual in the current surgical era. Once pulmonary blood flow is established, it is important to recognize that systemic oxygen saturation is related to the amount of flow into the pulmonary circulation. A very low pulmonary vascular resistance and conversely high systemic vascular resistance can result in low cardiac output despite a high saturation. The patient has an obligatory right-to-left shunt at atrial level, hence a very high saturation usually reflects an enormous amount of pulmonary flow. The resulting low diastolic pressure and low cardiac output syndrome can result in compromised splanchnic and renal flow as well as ongoing acidosis and, in the extreme, cardiogenic shock. In addition, this physiology can compromise oxygen delivery to the aortocoronary circulation resulting in myocardial ischemia.

Surgical

Surgical and other catheter-based interventional therapies have continued to change with an understanding of the heterogeneity of this disorder. The diagnostic and therapeutic algorithms are now quite diverse, depending on a wide number of morphologic variables (5,58–62). Among some centers, primary cardiac transplantation also is considered particularly when the coronary artery anatomy is complex. In evaluating an individual patient with this disorder and assuming a neonatal presentation, different surgical strategies will be derived for the patient with massive cardiomegaly and a right-to-left

Figure 41.12. Functional pulmonary atresia in a newborn with pulmonary atresia and intact ventricular septum. The upper panel demonstrates retrograde systolic flow in the main pulmonary artery (MPA); the lower panel shows the systolic regurgitation through the pulmonary valve. LA, left atrium; RV, right ventricle.

ventricular pressure ratio below 1.0 than for the neonate with a diminutive right ventricle and ventriculocoronary connections as the former carries with it very poor outcomes.

Most infants with PA and IVS will have some degree of right ventricular hypoplasia and hypertension, and thus the initial surgical considerations should include the following:

1. Is the patient ultimately a candidate for a complete biventricular (including the so-called one-and-a-half ventricle) repair or a univentricular total cavopulmonary (Fontan) palliation?
2. Does the patient have ventriculocoronary connections? If so, how much of the myocardial perfusion is right ventricular dependent?
3. Does the patient have an infundibulum? Is there a main pulmonary trunk in continuity with the imperforate pulmonary valve?
4. Is left ventricular function preserved?

Ideally, one would like to achieve a biventricular repair in these patients, and the initial approach should allow right ventricular decompression by some form of right ventricular outflow tract reconstruction, whether surgical pulmonary valvotomy,

outflow tract patch, or catheter-based perforation and dilation of the pulmonary valve. If there are ventriculocoronary connections and the majority or the entirety of the coronary circulation is right ventricular dependent, clearly the patient should be placed on a univentricular palliation algorithm (63–65).

Data in a small number of patients have suggested that the right ventricle can enlarge if it is satisfactorily decompressed; however, no single institution has a sufficient number of contemporarily treated patients in the current era to provide consistent therapeutic recommendations. When evaluating the literature, it is important to consider whether growth is measured in terms of absolute changes in size or normalized to growth of the individual. Conventional wisdom has suggested that if the right ventricle outlet remains atretic, growth of the right ventricle is unlikely to occur, and thus a two-ventricle heart is unlikely to be achieved (61).

In a prospective, multi-institutional investigation, 171 neonates with PA and IVS were studied between January 1, 1987, and January 1, 1991 (5). Multivariable analysis of the data showed that small diameter of the tricuspid valve, a coronary circulation that was severely right ventricular dependent, birth weight, and date and type of initial surgical procedures were

Figure 41.13. A: Four-chamber apical view depicting a dilated right coronary artery (RCA) in the atrioventricular groove. B: Color flow Doppler of the same image confirms flow within the vessel. Figure 41.15. This right ventricle (RV) angiogram demonstrates dense opacification of the left anterior descending coronary artery (*arrow*) but no filling of the aortic root. This should be interpreted as consistent with lack of a proximal aortocoronary connection. The diminutive right ventricle is unipartite.

risk factors for time-related death. Data from this study indicated that 49 patients had a surgical valvotomy with or without systemic-to-pulmonary artery shunt as the initial procedure, 42 had a transannular patch, and 71 had only a systemic-to-pulmonary artery shunt. Survival for all procedures was 81% at 1 month after the first intervention and 64% at 4 years. Eighteen percent of living patients had received univentricular palliation within 3 years and 32% a two-ventricle repair. The remainder, 50%, had still incompletely separated pulmonary and systemic circulations. What, then, is the optimal initial surgical therapy? A systemic-to-pulmonary artery shunt has a low initial surgical mortality, but this procedure does not promote the possibility of ventricular growth. Ideally, one would like to perform a valvotomy alone, but many, especially those with a small right ventricle and tricuspid valve, will require a systemic shunt as well. Even many patients treated by initial surgical transannular pulmonary outflow tract repair required an additional shunt.

To survive, some patients will require a combination of a transannular right ventricular outflow tract patch and an arterial shunt as the initial surgical procedures. A proportion of these patients will go on to successful closure of the interatrial communication as well as closure of the shunt, thus resulting in a two-ventricle repair. In others, the tricuspid valve may not grow and repair will have to be combined with a bidirectional cavopulmonary connection, perhaps in concert with pulmonary valve replacement (66,67). In this latter group of patients, it may be necessary to try to balloon-occlude the atrial septal defect temporarily and to measure cardiac output as well as right atrial pressures before, during, and after occlusion. It is likely that a proportion of these patients can be treated in the cardiac catheterization laboratory with

Figure 41.16. A unipartite right ventricle (RV) whose tricuspid Z value was -3.5 . Extensive ventriculocoronary connections are demonstrated by frontal and lateral right ventriculograms. The anterior descending coronary artery demonstrates numerous caliber changes (*arrows*) consistent with arterial obstructions. (See also Fig. 41.6.) The connection from RV to the coronary circulation is noted by the *curved arrow*. Left: anteroposterior view. Right: lateral view.

Figure 41.17. Right ventricular angiograms in a patient with pulmonary atresia and absence of an anterior descending coronary artery. **A:** The lateral projection demonstrates the presence of a communication between the right ventricle and the coronary artery. Unlike Figure 41.14, the ostium of the coronary artery is not atretic (*arrow*). The left main coronary artery continues posteriorly as the circumflex vessel (Cx). **B:** In the frontal projection, the aortic origin of the left coronary artery is obscured; however, a network of fine vessels within the leftward and anterior myocardium is delineated. Left (**C**) and right (**D**) axially angulated projections fail to demonstrate an anterior descending vessel. This was confirmed on subsequent selective angiography.

catheter occlusion of the atrial septal defect and occlusion of the systemic-to-arterial shunt. Some patients likely will require a so-called one-and-a-half ventricle repair, with the bidirectional cavopulmonary shunt effectively unloading the small right ventricle and potentially obstructive tricuspid valve. Decompression of the hypertensive right ventricle can be accomplished by removing the tricuspid valve or performing a pulmonary valvotomy. Although both these maneuvers usually are considered within the domain of surgical influence, both can now be accomplished in the cardiac

catheterization laboratory. Most centers have abandoned tricuspid valve avulsion or excision and right ventricular thromboexclusion.

The CHSS database was reviewed for 408 neonates with PA and IVS from 33 institutions (68). Survival for the cohort was 77% at 1 month, 70% at 6 months, 60% at 5 years, and 58% at 15 years. The morphologic heterogeneity is illustrated by the prevalence of described end points at 15 years with 33% achieving a biventricular repair, 20% a univentricular Fontan, 5% a one-and-a-half ventricular palliation, and 2%

Figure 41.18. **A:** Right ventricular angiogram demonstrates the presence of a left coronary artery fistulous connection (*arrow*); however, the extent to which the right ventricle provides exclusive myocardial perfusion is not delineated. **B:** Retrograde selective injection of the left coronary artery in a long-axis oblique projection in the same patient clearly demonstrates the left ventricular myocardium perfused by the aortocoronary supply without significant coronary artery stenosis or occlusion.

Figure 41.19. Three-dimensional rotational right ventricular angiogram depicting coronary artery connections for the right ventricle (RV). Epicardial coronary arteries (*arrows*) demonstrate interruptions.

a transplantation. A further 2% were alive without definitive repair or palliation, and the remaining 38% died before achieving definitive repair or palliation. Not surprisingly, the end state was predicted by the adequacy of the right-sided structures, the degree of aberrancy of the coronary circulation, a low birth weight, and the degree of tricuspid regurgitation. An important observation was the improved 5-year survival with surgical era reflected by an increase from 49% born to 1987, to 63% in 1992, and to 79% in 1992 to 1997. This improvement in surgical era is also supported by single institutional reviews (69,70). The documented improvement in outcome over time is, most likely, a reflection of improved understanding of neonatal and pediatric physiology and intensive care in the pre- and postoperative management of these medically complex patients and is important to consider when considering the literature.

Management of the Patient Whose Coronary Circulation Is in Large Part Right Ventricular Dependent

Decompression of the right ventricle in the setting of a significantly dependent myocardial circulation is unwise as any procedure that reduces right ventricular systolic pressure or blood entering the right ventricle will unmask any right ventricle-dependent coronary circulation with massive, if not fatal, myocardial ischemia. These maneuvers include pulmonary valvotomy or right ventricular outflow tract reconstruction, tricuspid valve excision or catheter avulsion, and right ventricle thromboexclusion. These patients should undergo a ductal stent or a systemic-to-pulmonary artery shunt as the initial procedure, with a balloon atrial septostomy given consideration in the cardiac catheterization laboratory. The patient should be placed on a program eventuating in a one-ventricle total cavopulmonary (Fontan) palliation. In some centers, these patients are considered for primary cardiac replacement, especially if the coronary anomalies are particularly severe.

The lateral-tunnel or extracardiac modifications of the total cavopulmonary (Fontan) principle with pulmonary venous blood having access to the tricuspid valve, right ventricle, and thus in a retrograde fashion to the coronary arteries have been applied to patients with an extremely disordered coronary circulation (71,72). It is probable that this approach is ultimately a bridge to cardiac transplantation. Indeed, some patients exhibit globally reduced left ventricular function that cannot be improved by a variety of medical and surgical maneuvers and are destined for cardiac replacement. Table 41.5 outlines some approaches to the management of patients with PA and IVS and an abnormal coronary circulation.

Extreme Ebstein-like/Dysplastic Tricuspid Valve and Organic Pulmonary Atresia

The previous conventional therapies of attempting to repair or replace the tricuspid valve and pulmonary valvotomy with or without a surgical shunt have carried a poor prognosis. Contemporary approaches include cardiac transplantation and conversion to tricuspid atresia and construction of a systemic-to-pulmonary artery shunt with a later cavopulmonary palliation. Relatively little experience has been gained in the transplantation of infants with this particular variety of the lesion, but Starnes et al. (73) prepared an interesting

TABLE 41.5 Current Surgical Strategies Based on Abnormal Coronary Artery Anatomy

Coronary Artery Anomaly	Surgical Strategy
Absence of bilateral proximal coronary-aorto connections	Consider transplant versus high-risk shunt or ductal stent
Absence of aorto-left coronary artery connection	Consider transplant versus high-risk shunt or ductal stent
Severe coronary-cameral steal	Consider fistula occlusion with RV decompression
Ventriculocoronary connections with no stenosis or interruption	Decompress RV
Mild distal stenoses or ectasia in presence of ventriculocoronary connections	Decompress RV (but at higher risk than in absence of stenoses/interruption)
Proximal LAD interruption, proximal RCA stenosis, significantly RV-dependent myocardial perfusion	Shunt or ductal stent, univentricular track

LAD, left anterior descending; RCA, right coronary artery; RV, right ventricle.

alternative to conventional surgical wisdom with their surgical conversion of these patients to tricuspid atresia, construction of a systemic-to-pulmonary arterial anastomosis with a later Fontan.

Transcatheter Techniques in the Management of Pulmonary Atresia and Intact Ventricular Septum

Surgical algorithms for patients with PA and an IVS focus on the probability of avoiding the total cavopulmonary (Fontan) circulation. Many clinicians advocate establishing continuity from right ventricle to pulmonary artery with a right ventricular outflow tract patch or valvotomy early in the patient's course to encourage growth of the hypoplastic ventricle as a means of achieving a biventricular or so-called one-and-one-half ventricle repair in carefully selected patients. This approach mandates prediction of the ventricle with the potential for growth and exclusion of patients with a right ventricle-dependent coronary circulation who are at risk for

ischemic myocardial injury following ventricular decompression. Initial results have been encouraging, but surgical mortality remains relatively high. The ideal patient would have a tripartite right ventricle of near normal size with valvar PA and a well-developed pulmonary arterial circulation (Fig. 41.20).

Whereas several factors may contribute to high surgical mortality, myocardial insult incurred at surgery with ventriculotomy and reperfusion injury in the setting of preexisting myocardial fiber disarray and diffuse fibrosis may play an important role. This has encouraged some centers to complement the surgical algorithm with interventional catheterization techniques to achieve right ventricular to pulmonary artery continuity. Transcatheter perforation of the atretic pulmonary valve with subsequent balloon dilation can be employed as an alternative to surgical valvotomy in selected patients. Laser energy applied to the tip of a small wire has allowed controlled perforation of the atretic valve tissue and has been achieved in several patients with good results in short-term follow-up (74); however, laser therapy carries the disadvantages of increased risk to staff, the requirement for protective goggles, limited

Figure 41.20. A: Right ventricular angiogram in frontal projection confirms a hypoplastic tripartite right ventricle with pulmonary atresia. B: Retrograde injection into the main pulmonary artery confirms membranous atresia of the pulmonary valve. C: Perforation of the membranous valve is achieved (in this case assisted by radiofrequency energy), thus allowing a balloon catheter to be positioned across the valve and inflated. D: Repeat angiography immediately following balloon valvotomy demonstrates a patent right ventricular outflow tract.

portability, and considerable capital expense in the setting of an uncommon defect.

Radiofrequency energy, which can safely achieve well-defined lesions of coagulation necrosis, is now widely applied in the treatment of many cardiac dysrhythmias. Use of this energy source to perforate atretic valve tissue has the advantages of being considerably less expensive, more portable, and less hazardous to staff. Radiofrequency wires capable of confining the energy to the tip have been developed for this lesion based on proven utility in recanalization of arterial occlusions, and results have been encouraging. Where radiofrequency or laser wires have not been available, other means of attaining perforation have been used, including mechanical wire perforation and standard electrode catheters.

The reported literature attests to the fact that it is possible to establish continuity from right ventricle to the pulmonary artery in the catheter laboratory and thus avoid the need for cardiopulmonary bypass in many patients (21,38,74–96). The long-term results of the procedure remain largely unknown. Although early success defined by the ability to achieve perforation has been demonstrated in >80% of patients reported, controversy remains regarding the growth of the right ventricle and outflow tract over time. In evaluating the literature, one must be careful to distinguish an absolute increase in the size of an anatomic structure such as the tricuspid valve from that of the indexed size. As an example, the tricuspid valve appears to enlarge over time with transcatheter perforation of the tricuspid valve (97); however, the indexed Z value does not appear to change significantly (21). In addition, the need for prolonged prostaglandin infusion, creation of a systemic-to-pulmonary artery shunt, or implantation of a stent in the ductus arteriosus to achieve the same end is a common occurrence in this group of patients and occurs in 33% to 58%. Notably, however, these secondary interventions do not require the use of cardiopulmonary bypass that may be important when one considers the influence of myocardial abnormalities on outcome. To further frustrate clinicians, the timing of secondary intervention to increase pulmonary blood flow can be difficult to assess after transcatheter valvotomy as it appears that days to weeks are required for the decompressed right ventricular compliance to improve. If a systemic-to-arterial shunt is created too early, one can be in the paradoxical situation of embolizing the same shunt in the future once the ventricular compliance has improved. To further complicate matters, a systemic shunt in the setting of severe pulmonary insufficiency and tricuspid insufficiency can result in an ineffective “circular” circulation where flow of systemic arterial blood courses through the shunt to the right ventricle, regurgitates through the tricuspid valve to the right atrium, and courses across the atrial septum to the left atrium where the process repeats. Effective pulmonary blood flow is decreased, and the left ventricle is exposed to physiology similar to a large arteriovenous fistula. Myocardial oxygen demand is increased, diastolic aortic pressure is borderline, and the patient is cyanotic, all of which contribute to progressively worsening myocardial performance. Indeed, this circulation may be more likely to occur with a stented ductus arteriosus as the flow through the shunt is directed through the perforated valve to the ventricle as opposed to the modified Blalock-Thomas-Taussig shunt where flow to the ventricle must take a more indirect path through the pulmonary artery to the right ventricle. Still, consideration may be given to stenting the ductus concurrent with valve perforation in selected cases (98). It seems that the best outcomes are clearly achieved with an individualized cooperative creative transcatheter surgical approach including so-called hybrid interventions (99–101).

The role of transcatheter techniques in the management continuum of these patients is in evolution; however, com-

parison to surgical outflow tract reconstruction is, at least in one series, favorable (75). With a relatively small number of patients affected by this condition, there is much to be learned from a multicentered approach to collecting a longitudinal experience in a combined transcatheter and surgical approach to a challenging clinical problem. Whereas a percutaneous approach may avoid or delay the use of cardiopulmonary bypass in the newborn period, it remains to be seen whether it results in a decrease in long-term morbidity or mortality.

TREATMENT OF THE ADULT

It should be clear from the preceding discussions that there is a great anatomic and physiologic diversity of patients surviving into adulthood with PA and IVS. Patients may have achieved a biventricular circulation, a univentricular circulation in the form of a total cavopulmonary circulation, or a permanently palliated shunted state. Outcome data for the adult population are few, and reported results may even be counterintuitive. For instance, it is unclear whether a biventricular circulation holds advantage over a univentricular circulation in the assessment of exercise capacity and indeed may be more influenced by pulmonary than cardiac issues as aerobic capacity appears to decrease in both groups (102). Myocardial perfusion abnormalities persist well beyond definitive repair (palliation) (103). In the adult with a biventricular repair, right ventricular restriction may favor better physiologic status; however, many patients will go on to require a pulmonary valve replacement to restore competency of the right ventricular outflow tract (104,105). In a recent study (106) of 20 survivors into adulthood (19 to 39 years old) with Fontan ($n = 7$), biventricular ($n = 8$), and palliated shunts ($n = 5$), there were 5 deaths at a mean age of 32 years. All patients required interventions in adulthood with tricuspid and pulmonary valve replacements being very common in the biventricular group. Atrial arrhythmias occurred frequently in the cohort (80%) but ventricular arrhythmias were not uncommon (15%). Although the literature is sparse, it is clear that all of these patients will require continued specialized tertiary and quaternary follow-up, specialized intervention, arrhythmia management, and ancillary support as they reach adulthood. The value of registry data to guide the care of the growing population of adults with congenital heart disease cannot be overstated.

SUMMARY

Congenitally malformed hearts with PA/IVS demonstrate clinically important heterogeneity of the right-sided cardiac structures, the coronary circulation, and the myocardium. Fetal recognition of this condition will affect newborn epidemiology due to the influence of elective termination of pregnancy (8,107,108). Rarely, survival beyond the neonatal period has been documented due to persistent patency of the arterial duct or more rarely by associated conditions that preserve pulmonary blood flow such as an aortopulmonary window or coronary to pulmonary artery connections. A variety of surgical and transcatheter interventions exist that culminate in eventual biventricular repair or in the univentricular total cavopulmonary circulation. An intermediate form of palliation exists in the form of the so-called one-and-a-half ventricle repair where the right ventricle with a patent outflow tract is effectively unloaded with a bidirectional cavopulmonary connection, although the long-term advantage of this circulation remains to be seen (66,109–112). Where some have questioned whether it is possible to improve outcomes, the literature

supports cautious optimism by demonstrating improved survival with more recent era of intervention. Understanding the nature of the coronary artery circulation, the application of a one ventricle or one-and-a-half ventricle repair, and the application of radiofrequency catheter perforation of the imperforate pulmonary valve all have contributed to increased salvage of these infants, although there is still much to be achieved. Intrinsic, indeed congenital, abnormalities in the vascular supply and myocardial architecture ultimately may argue for a poor outcome in at least some of these patients. Sudden coronary death remains a worrisome long-term concern, but establishing risk is unclear (113). The role for cardiac transplantation of the neonate is unclear; however, consideration should be given to the patient with severe Ebstein-like malformation and severe tricuspid insufficiency as these patients continue to represent the worst surgical outcomes. Adult survivors will require specialized follow-up and frequent reintervention. It is clear that the anatomic and physiologic diversity of this patient population represented by the neonate will continue to challenge treatment strategy into adulthood.

Pulmonary Atresia and Ventricular Septal Defect

Patrick W. O'Leary ■ William D. Edwards ■ Paul R. Julsrud ■ Harold MacDonald Burkhart

The combination of pulmonary valve atresia and ventricular septal defect (PA-VSD) can be considered to be the most severe form of tetralogy of Fallot (TOF). However, unlike TOF, the right ventricular outflow tract (RVOT) ends blindly, and all of the right ventricular stroke volume is directed to the aorta via the ventricular septal defect (VSD). In addition, the pulmonary arterial architecture is much more complex in PA-VSD than in TOF. As a result, delineating these arterial complexities and planning the most effective management strategy are more difficult for this lesion than for TOF. Although the pulmonary arteries in TOF occasionally are hypoplastic and can show anomalies of peripheral arborization, more commonly they are normal. Also, in TOF, systemic-to-pulmonary collateral vessels are extremely unusual. In PA-VSD, however, often there are severe abnormalities in the size and distribution of the pulmonary arterial branches and well-developed systemic collateral vessels that supply all or portions of the lung parenchyma. In extreme cases, the pulmonary vascular tree can even be composed of discontinuous segments, each with an independent source of flow.

PA-VSD accounts for about 2% of congenital heart disease (CHD). It is one of the common causes of cyanosis and hypoxemia in the neonate. PA-VSD is slightly more prevalent in male than in female infants. In the Baltimore-Washington Infant Study (BWIS), a prevalence of 0.07 per 1,000 live births was observed for PA-VSD (1,2), and PA-VSD accounted for 20.3% of all forms of TOF.

Although corrective operation was first performed >30 years ago for patients with well-developed pulmonary arteries, patients with severe abnormalities of the pulmonary arteries initially were considered inoperable or only as candidates for surgical palliation. Surgical techniques have evolved to a stage that correction (with VSD closure) is possible for steadily increasing numbers of these patients.

ENVIRONMENTAL FACTORS AND GENETICS

Maternal diabetes, maternal phenylketonuria (PKU), and maternal exposure to retinoic acids and to trimethadione are associated with an increased risk of conotruncal defects in the infant (2–5). Investigators in the BWIS found that infants of diabetic women had nearly a 10-fold increased risk of developing PA-VSD (2).

Investigators have described families with multiple members with PA-VSD (6–11). In some families, each affected person has PA-VSD, whereas in other families, various types of conotruncal defects, or CHDs, occurred. Wulfsberg et al. (12) described one family in which two siblings from nonconsanguineous parents had PA-VSD. Der Kaloustian et al. (13) described two siblings of first cousins with PA-VSD. Other families had members with TOF and a spectrum of pulmonary valvular abnormalities or conotruncal defects. These reports

support different modes of inheritance and support a role for genetic factors in the etiology of PA-VSD. The recurrence risk for any individual family can vary tremendously, depending on the number of affected persons and whether the CHD is associated with a single gene defect or a chromosomal deletion.

Many patients with PA-VSD have genetic syndromes and extracardiac anomalies. In the BWIS, 8.3% of cases with PA-VSD had chromosomal anomalies; 11.7% were syndromic (mendelian and nonmendelian), and 6.7% had other single organ defects (2). Thus, only 73.3% of patients with PA-VSD had no recognized associated anomalies.

Investigators have identified the genetic cause of the DiGeorge/velocardiofacial syndrome (DGS/VCFS). The phenotype associated with the 22q11.2 deletion syndrome (or DGS/VCFS) is highly variable and includes CHD, palatal anomalies, hypocalcemia, immunodeficiency, speech and learning disabilities, renal anomalies, psychiatric problems, and distinct facial features (14,15). The clinical features vary, not only among unrelated persons, but also among family members sharing the same 22q11.2 deletion. Furthermore, the clinical features can be subtle and go unrecognized. Eight percent to twenty-three percent of patients with TOF have a 22q11.2 deletion (16–19).

In a European collaborative study, 10% of patients with a 22q11 deletion had PA-VSD (20). In two studies, it was found that a 22q11.2 deletion occurred in patients with PA-VSD more frequently than in patients with TOF (21,22). In a third study, however, no statistical difference in the frequency of a 22q11.2 deletion in patients with PA-VSD was found compared with TOF/pulmonary stenosis (PS) (19). Additional vascular anomalies, such as aortopulmonary collaterals, right aortic arch, or aberrant subclavian artery, occur more frequently in patients with PA-VSD and a 22q11.2 deletion than in those without a deletion (19,23). Branch pulmonary arteries are smaller in patients with a 22q11.2 deletion than in those without the deletion (22,24). Clinical outcomes have been worse for patients with PA-VSD and the 22q11.2 deletion (25).

EMBRYOLOGY

During early gestation, the lungs develop from the foregut, and therefore their nutrient blood supply arises initially from the paired dorsal aortas. About day 27, the arterial branches of the paired sixth aortic arches form an anastomosis with the pulmonary vascular plexus. As a result, the lungs initially have a dual blood supply. During normal development, the branches from the sixth aortic arches enlarge, and those from the descending thoracic aorta become smaller. The larger vessels will form the true pulmonary arteries and deliver blood to the alveoli or capillaries that are derived from the pulmonary vascular plexus. The smaller vessels form the nutrient

bronchial arteries. Bronchopulmonary anastomoses persist but are of small caliber and tend to disappear postnatally. In the normal heart, supply to the derivatives of the sixth aortic arches (the true pulmonary arteries) will be the right ventricle (RV). However, in PA/VSD there is complete discontinuity of the RV and the central pulmonary arteries (Fig. 42.1). Therefore, the source of pulmonary blood supply is variable (26,27).

In a sense, the embryologic development of the pulmonary arteries is analogous to that of the pulmonary veins. Thus, the variable origins of pulmonary blood supply in cases of PA-VSD are analogous to the variable sites of drainage in total anomalous pulmonary venous connection. When the normal connection between the heart and pulmonary arteries does not develop, the alternate blood supply to the lungs can be from the ductus arteriosus, bronchial arteries, or other systemic-to-pulmonary collateral arteries.

PATHOLOGY

The extent of pulmonary artery atresia is quite variable and involves the central pulmonary arteries (i.e., those outside the lungs) either proximally and/or distally. The atretic arterial segment can be recognized as a solid elastic cord in about 75% of the cases but is unidentifiable in the other cases. Most commonly, the pulmonary valve and the proximal portion of the pulmonary trunk (PT) are involved. Rarely, only the

pulmonary valve is imperforate. The central right and left pulmonary arteries and/or the segmental pulmonary arteries can be confluent or nonconfluent. In PA-VSD, the blood supply to the lungs is entirely from the systemic arterial circulation. The sources are the ductus arteriosus, systemic-to-pulmonary collateral arteries (henceforth designated simply as collateral arteries), occasionally a coronary artery, and plexuses of bronchial or pleural arteries (26). Ductal and collateral sources may coexist in the same patient but only rarely coexist in the same lung (26). A single systemic arterial source to a lung is termed a unifocal blood supply, whereas multiple sources are termed multifocal blood supply.

The caliber of the central pulmonary arteries varies considerably and appears to be directly related to the amount of blood flow (26). When the ductus or collateral arteries connect proximally to the central pulmonary arteries or their lobar branches, the central vessels may be only mildly hypoplastic or even normal in size. In contrast, when multiple collateral arteries are anastomosed more distally at segmental or subsegmental levels, the central pulmonary arteries tend to be quite hypoplastic. Furthermore, stenosis of the systemic arterial channels, either congenital or acquired, can be associated with hypoplasia of the central pulmonary arteries (26).

The various patterns of intrapulmonary arterial distribution may be quite complex and are determined primarily by the types of systemic arterial blood supply (26). When a ductus supplies confluent central pulmonary arteries, the intrapulmonary arteries of both lungs are normal. When nonconfluent central pulmonary arteries are present, however, the lung

Figure 42.1. Pulmonary atresia and ventricular septal defect. **A:** Anterior view of unopened specimen from an 18-year-old patient shows dextroposed aorta (Ao), right aortic arch, and severely hypoplastic pulmonary trunk (PT) and left pulmonary artery (LPA). **B:** Opened right ventricle from a 1-year-old patient shows VSD (asterisk) cradled by limbs of septal band (SB) and left ductal origin (D) of the left pulmonary artery (LPA). **C:** Posterior view of mediastinal structures from a 4-year-old child with pulmonary situs inversus, right aortic arch, and right atrial isomerism shows origin of large systemic collateral artery (arrow) to left lung from descending thoracic aorta. **D:** Anterior view of right aortic arch from an 8-year-old child shows mirror-image brachiocephalic branching, aberrant retroesophageal left subclavian artery (LSA), and origin of two small collateral arteries (arrows) and one large trifurcating collateral artery (asterisk). (LCCA, left common carotid artery; LV, left ventricle; RAA, right atrial appendage; RCCA, right common carotid artery; RSA, right subclavian artery; RV, right ventricle; Tr, trachea; TV, tricuspid valve.)

supplied by a ductus will have a unifocal blood supply and a normal arterial distribution, but the contralateral lung usually has a multifocal blood supply and a fragmented pulmonary arterial distribution (so-called *arborization abnormality*) (26). When both lungs are supplied by multiple collateral channels, intrapulmonary arborization abnormalities are the rule (26), and a ductus is absent.

The ductus arteriosus, when present, usually is a unilateral structure and is associated with confluent pulmonary arteries in >80% of cases (26). Rarely, bilateral ductus may occur with nonconfluent pulmonary arteries. Unlike collateral arteries, the ductus does not branch before joining the central pulmonary arteries, and it tends to be less tortuous than collaterals. Because the ductus is widely patent during fetal life, the pulmonary arteries may be of normal size at birth. However, normal postnatal ductal narrowing usually occurs and produces distal stenosis in 35% to 50% of cases (26). As a result, blood flow to the lungs is diminished, and relative hypoplasia of the pulmonary arteries becomes more severe as the child grows.

Collateral arteries, when present, arise most commonly from the descending thoracic aorta, less commonly from the subclavian arteries, and rarely from the abdominal aorta or its branches or from the coronary arteries (26–28). Their number varies from 1 to 6, and their diameter ranges from 1 to 20 mm (26). Stenoses are present in nearly 60% of collateral arteries and tend to occur near the aortic or intrapulmonary anastomoses. The stenoses may be discrete or segmental, congenital or acquired (26). Anastomoses between the central pulmonary arteries (or their branches) and the collateral arteries are observed in about 40% of patients and may occur at the hilum or within the lung (26,29). In the remaining 60%, the collateral arteries enter the pulmonary hilum, travel with the bronchi as pulmonary arteries, and supply a variable number of bronchopulmonary segments (26). Although the central pulmonary arteries are confluent in about two-thirds of the cases, they usually supply only a portion of each lung owing to the coexistence of multiple collateral arteries and arborization abnormalities (26).

Small arterial plexuses that follow the bronchi or spread over the pleural surfaces may be apparent angiographically in more than half of the patients (26). They may arise from the aorta and its thoracic branches or from the systemic collateral arteries (26). It is thought that these vessels enlarge and proliferate postnatally in response to regional reductions in blood flow.

The ductus arteriosus is a precarious sole source of pulmonary blood supply, and its tendency to close necessitates surgical intervention in early infancy in more than half of the cases. Collateral arteries appear to be a more stable source of pulmonary blood flow, presumably because of multiple numbers. However, stenosis of collaterals may develop progressively, and they may become inadequate as the patient grows. Furthermore, because of hyperperfusion of some bronchopulmonary segments and hypoperfusion of others in the same patient, the pulmonary vascular bed may exhibit various histopathologic lesions, ranging from hypertensive pulmonary vascular disease to stasis thrombosis (26).

The VSD may be membranous or infundibular. Because it is also a malignancy defect with an overriding aorta, it tends to be larger than isolated membranous or infundibular defects. Rarely, the VSD can be obstructed partially by accessory tricuspid valvular tissue (30).

Although equal biventricular origin may occur, the aorta usually arises predominantly from the RV (31). The ascending aorta characteristically is dilated, but the degree of dextroposition usually is less than with TOF (31). Aortic valve insufficiency may result from annular dilation or infective endocarditis. A right aortic arch is present in 26% to 50% of the cases (31).

The right atrium tends to be dilated and hypertrophied, and the left atrium usually is normal. A secundum atrial septal defect (ASD) or patent foramen ovale is present in about half of the cases (31). Generally, the tricuspid orifice is of normal size, but minor leaflet abnormalities occur commonly. The mitral valve orifice tends to be normal or mildly hypoplastic (31).

Right ventricular hypertrophy is moderate to severe. The infundibulum ends blindly and may range in length from normal to very short. In many instances, the displaced infundibular septum is fused to the right ventricular wall. The left ventricular wall thickness generally is normal, and the chamber size tends to be normal or somewhat small (31). Occasionally (usually in older patients), the left ventricle (LV) is hypertrophied and dilated.

In most cases, the origin and distribution of the coronary arteries are normal. However, the conus artery tends to be quite prominent (31). Coronary anomalies include high origin of the coronary ostia, coronary-to-pulmonary artery fistulas, and origin of the right coronary artery from the left anterior aortic sinus, coursing across the right ventricular infundibulum (31).

The sinus node is normal. The atrioventricular node occupies its normal position within the triangle of Koch. The non-branching proximal portion of the His bundle penetrates the central fibrous body and lies along the left ventricular aspect of the posteroinferior rim of the VSD. The His bundle is related closely to the rim of membranous VSD, but is relatively remote from the border of infundibular defects. The sheet-like left bundle branch spreads along the ventricular septal endocardium in a relatively normal fashion. However, the cord-like right bundle branch must travel through the septal musculature to reach its subendocardial position along the septal band (SB) (septomarginal trabecula). It may be bifid or form several aberrant branches (32). Pulmonary atresia and VSD may be associated with other anomalies, including a persistent left superior vena cava to the coronary sinus, anomalies of the coronary sinus, partial or total anomalous pulmonary venous connection, tricuspid stenosis or atresia, complete atrioventricular septal defect, D- or L-transposition of the great arteries, dextrocardia, and heterotaxia syndromes (31).

Clinical Features

A patient with PA-VSD often presents as a cyanotic newborn. The infant may do well for a day or two, as long as there is substantial blood flow through a patent ductus arteriosus (PDA), but then becomes increasingly hypoxemic as the ductus constricts. If there are insufficient systemic-to-pulmonary artery collateral vessels, closure of the ductus will be lethal. Use of prostaglandin E₁ is critical in the early neonatal period to maintain ductal patency and stabilize the patient prior to surgery.

Some neonates with PA-VSD are not severely hypoxemic, either because the ductus arteriosus remains patent or because systemic collateral vessels are sufficiently developed to provide adequate pulmonary blood flow. These babies may maintain good oxygenation for some time. However, over time, hypoxemia and cyanosis increase as the patient outgrows the relatively fixed sources of pulmonary blood flow.

On rare occasions, an infant with PA-VSD may have heart failure and signs of increased pulmonary blood flow. This occurs most commonly at 4 to 6 weeks of age after the pulmonary arteriolar resistance has decreased. The increased pulmonary flow can be due to a large PDA or large systemic-to-pulmonary artery collateral vessels. This may be difficult to control medically, and surgical intervention may be necessary. In patients with a large PDA, the pulmonary arteries usually are well developed, and early complete repair may be feasible.

In the group of patients with large collateral vessels, however, the true pulmonary arteries frequently are hypoplastic with arborization abnormalities making definitive correction more difficult.

Patients with microdeletion of 22q11.2 tend to have more complex collateral and pulmonary arterial anatomy than patients without this genetic abnormality. Absence or severe hypoplasia of the central pulmonary arteries and the presence of multiple major collateral arteries reduces the likelihood of successful biventricular repair in these patients (22).

The presentation of patients with PA-VSD who have had palliative surgical procedures is quite variable. In the absence of significant valve regurgitation, heart failure is uncommon. Most patients are somewhat cyanotic, and some patients may be severely hypoxemic. As patients outgrow shunts performed early in life, they become increasingly cyanotic. These shunts usually improve oxygenation, but complications of shunts include distortion and stenosis of pulmonary arteries and occasionally lead to pulmonary vascular obstructive disease. These vascular complications are common, particularly in patients who have had either a Waterston (the ascending aorta to the right pulmonary artery connection) or Potts shunt (descending aorta to the left pulmonary artery [LPA] connection). As a result, these procedures, for the most part, have been abandoned. The classic or modified Blalock-Thomas-Taussig shunt is the preferred palliative shunt. Alternatively, initial palliation can be accomplished by establishing a direct connection between the ascending aorta and the remnant of the main pulmonary artery (33) or creating a nonvalved connection between the RV and hypoplastic confluent pulmonary arteries leaving the VSD open. These procedures produce more rapid enlargement of the central pulmonary arteries than systemic-to-peripheral pulmonary artery shunts and also produce less distortion of the peripheral pulmonary arterial architecture. However, in patients with inadequate distal distribution from the central confluence or those with significant peripheral stenosis, these large central connections may produce segmental pulmonary hypertension. Due to the fact that all palliative approaches are associated with potential complications, a substantial number of older patients will have arterial beds damaged by these procedures. The frequency of late arterial distortion also emphasizes the need to obtain a detailed understanding of the pulmonary vascular architecture prior to planning an interventional strategy.

Physical Examination

Profound cyanosis usually is present in the early neonatal period. The rare exception is the patient with a large PDA or well-developed systemic-to-pulmonary artery collaterals. Cyanosis may be mild immediately after birth, but it increases in severity during the first several days of life as the PDA closes. It is common for the degree of cyanosis and the arterial oxygen tension to fluctuate considerably during the first several days as the ductus arteriosus constricts and relaxes. After the neonatal period, the degree of cyanosis in these patients usually increases gradually as the patient's growth outstrips the pulmonary blood flow.

Growth and development can be delayed, but if pulmonary flow is adequate and systemic hypoxemia is only mild, this may not be the case. If growth is delayed, one should suspect the presence of a 22q11.2 microdeletion. Heart failure caused by excessive pulmonary blood flow is uncommon in these patients; therefore, growth failure on this basis is infrequent.

The peripheral pulses and blood pressure usually are normal in the neonatal period, even with a PDA, because the runoff into the lungs is not excessive during the first few weeks of life. In cyanotic patients, the pulses are normal.

However, in patients beyond the first 4 to 6 weeks of age in whom pulmonary blood flow through a PDA, collaterals, or surgically created shunt is substantial, the pulses can be bounding, and only minimal cyanosis may be present. The cardiac impulse usually is most prominent at the lower left sternal border. The heart size is normal for patients with normal or decreased pulmonary blood flow.

There is a normal first heart sound and a single loud second heart sound. A systolic murmur may be audible along the lower left sternal border but usually is not more than grade 3/6 in intensity. Because the RVOT is atretic, there is no separate loud systolic ejection murmur at the upper left sternal border. This is in contrast to the finding in TOF with antegrade pulmonary blood flow. If a PDA is present, a continuous murmur usually is heard after the first 4 to 6 weeks of life. If systemic-to-pulmonary collateral vessels are present, continuous murmurs can be heard. These may be multiple and often are most prominent over the back because these vessels usually originate from the descending aorta.

Electrocardiographic Features

Right ventricular hypertrophy and right-axis deviation are the rule. In patients with increased pulmonary blood flow (a small subgroup), combined ventricular hypertrophy and left atrial enlargement may occur. Electrocardiography often helps to differentiate this condition from pulmonary atresia with intact ventricular septum (VS), in which right ventricular hypoplasia usually is present and diminutive anterior QRS forces with left ventricular preponderance occur.

Radiographic Features

The heart frequently has a characteristic appearance likened to the shape of a boot (*coeur en sabot*). This is due to levorotation of the heart, which produces a prominent, upturned cardiac apex, secondary to right ventricular hypertrophy. There is also a concavity in the region of the main pulmonary artery produced by underdevelopment of the subpulmonary infundibulum. The frequency of a right-sided aortic arch is greater in patients with PA-VSD (26% to 50% of these patients) than in those with TOF (20% to 25%). The pulmonary vascular markings usually have a heterogeneous reticular appearance that does not conform to the usual arborization pattern of pulmonary vessels. This appearance is caused by collateral arteries from the systemic circulation that frequently are quite large and supply blood to the pulmonary artery. In patients with small systemic collaterals, the lung fields may have diminished vascular markings. In the patient with a large PDA and normally developed central pulmonary arteries, chest radiography shows enlarged central pulmonary arteries with increased peripheral vascularity.

Echocardiographic Features

Echocardiography usually provides the initial diagnosis, can determine the presence (and size) of a central pulmonary arterial confluence, can detect large collateral vessels, and can define many associated cardiovascular malformations. Echocardiographic techniques cannot completely delineate the distal pulmonary arterial tree or the sources of pulmonary arterial supply. Therefore, cardiac catheterization is necessary prior to definitive repair.

The 2-D echocardiographic appearance of PA-VSD is similar to that of TOF. Parasternal long-axis scans in both malformations show a large aortic valve that overrides a malaligned VSD (Fig. 42.2). The infundibular portion of the

Figure 42.2. This parasternal long-axis image from a patient with PA-VSD demonstrates a large malalignment VSD (*VSD) and an overriding aortic valve. These features are also present in tetralogy of Fallot and truncus arteriosus. (Ao, aortic root; LA, left atrium; LV, left ventricle; RV, right ventricle; VS, ventricular septum.)

VS is anteriorly malpositioned. The difference between these malformations is that the patient with TOF has a patent, although hypoplastic, RVOT anterior to the malaligned infundibular septum. This outflow tract is in continuity with the main pulmonary artery. In contrast, the infundibular septum has fused with the right ventricular free wall in patients with PA-VSD, and there is no separate outflow from the RV. All of the RV stroke volume enters the overriding aorta via the VSD. Another malformation that shares some characteristics with PA-VSD is truncus arteriosus. The distinguishing feature between these two anomalies is that in truncus arteriosus, the pulmonary arteries arise directly from the posterolateral aspect of the truncal root prior to the arch.

Echocardiographic scans from the suprasternal notch and high parasternal windows (both right and left) frequently provide important information about the size and status of the proximal pulmonary arteries. When the pulmonary arteries are confluent and clearly identified by echocardiography, newborns with ductal-dependent pulmonary blood flow can undergo a palliative systemic-to-pulmonary artery shunt procedure without cardiac catheterization (34,35). The 2-D echocardiographic evaluation of these features can be difficult when the pulmonary arteries are nonconfluent, the pulmonary arteries are extremely hypoplastic, or multiple collateral arteries are present in the area of the confluence. In these situations, color flow imaging markedly enhances evaluation of the pulmonary and collateral arteries (35). This technique has been especially helpful in neonates with hypoplastic but confluent pulmonary arteries (35,36). Regardless of the quality of echocardiographic data available, we believe that angiography is required for a complete assessment of the pulmonary arterial tree in most patients with PA-VSD prior to attempting definitive biventricular repair with VSD closure.

Although all collateral arteries cannot be defined using echocardiography, their presence should be noted and their origins delineated as precisely as possible. Knowledge of an unusual origin of a collateral vessel (such as from the abdominal aorta, a brachiocephalic artery, or a coronary artery) (Fig. 42.3) can simplify subsequent cardiac catheterization and angiocardiographic procedures.

Figure 42.3. This modified parasternal short-axis scan demonstrates an unusual origin of a collateral artery. The right coronary artery gave rise to a large coronary-to-pulmonary artery fistula (*Fistula). This fistula supplied most of the flow to the pulmonary artery confluence. Ao, aortic root; LA, left atrium; RA, right atrium.

Echocardiographic examinations can define many of the other abnormalities associated with conotruncal malformations. The position of the malalignment VSD, usually either membranous or infundibular, can be determined. ASDs and additional muscular VSDs can be detected with 2-D and color flow imaging. Short-axis parasternal and subcostal scans have been helpful in detecting coronary artery abnormalities, especially in neonates. Color flow imaging and continuous wave Doppler techniques allow serial noninvasive assessments of surgically created shunts and right ventricular-to-pulmonary artery conduits (37,38). Suprasternal notch scans define the sidedness and branching pattern of the aortic arch.

Cardiac Catheterization and Angiocardiography

Patients with small central pulmonary arteries or multiple sources of pulmonary flow should have cardiac catheterization for pulmonary angiographic mapping before definitive repair. For the neonate undergoing palliation, it is our policy to refer patients with small, but echocardiographically detectable, centrally confluent pulmonary arteries for a shunt to establish a reliable source of pulmonary blood flow without catheterization. These patients, who often have hypoxemia and cyanosis in the first few days of life, are treated with prostaglandin E₁ to maintain ductal patency until they can have an operation. In infants who require more pulmonary blood flow and in whom no proximal pulmonary arteries can be visualized echocardiographically, catheterization and angiography are performed to determine the source of pulmonary blood flow and to define the possible surgical options to increase pulmonary blood flow.

Before a patient with PA-VSD and complex arterial anatomy can be considered for a definitive operation, cardiac catheterization is mandatory to delineate the size and distribution

of the true pulmonary arteries and to ascertain the extent of collateral blood supply to the lungs. Right atrial pressures are normal unless tricuspid regurgitation is present, and there is no increase of oxygenation at the atrial level unless an associated ASD is present. RV pressure is equal to the LV pressure because of the large VSD. Since the RVOT is atretic, the catheter cannot be advanced into the pulmonary arteries from the RV, but can be manipulated easily from the RV through the VSD into the aorta. Aortic pressure is normal if pulmonary blood flow is normal or decreased. Widened pulse pressure may be present if there is a large runoff into the lungs through a PDA or a previously constructed shunt. Systemic arterial blood oxygen desaturation is present, and the degree depends on the volume of pulmonary blood flow.

The true pulmonary artery pressure and resistance are normal in most instances. In a few cases, however, patients with a large PDA, a large communication between a systemic collateral vessel and the true pulmonary arteries, a large fistula connecting the coronary artery to the pulmonary artery, or a shunt anastomosis that is too large (particularly common in Waterston and Potts shunts) have increased pulmonary artery pressure. These patients are at risk for developing pulmonary vascular obstructive disease. In such cases, usually it is easy to enter the true pulmonary arteries through the large communication, measure the pressure, and estimate pulmonary flow by the Fick principle. With this information, pulmonary arteriolar resistance can be calculated.

Angiocardiography is useful during the preoperative evaluation of these patients. Documenting the existence of multiple VSDs and anatomy of the coronary arteries is extremely important, particularly in infants. Ventricular and aortic root angiography should be done if this information is unavailable from noninvasive imaging studies. Compound angulated views greatly enhance the angiographer's ability to demonstrate this anatomy (39). Ventriculography should be performed with an injection into the left ventricular cavity while the cameras are positioned to record a 70-degree left anterior oblique view with 20 degrees of cranial angulation. This projection displays the middle portion and most of the upper interventricular septum tangentially. Figure 42.4 illustrates this view and demonstrates the superiorly located malaligned VSD and exclusion of additional septal defects. Although the coronary artery anatomy can be visualized during a ventricular injection, it is better defined by an aortic root angiogram and a 70-degree left anterior oblique view (with or without 20 degrees of cranial angulation). This projection identifies the relevant coronary artery anatomy. Of surgical importance is the origin of the left anterior descending coronary artery from the right coronary artery, which occurs in approximately 5% of patients (39). It is particularly important to define the coronary artery preoperatively if there have been previous surgical procedures resulting in pericardial adhesions that obscure the coronary anatomy. We found it necessary to do selective injection of individual coronary arteries only in patients with large aortic roots and high rates of flow (particularly in patients with Waterston shunts).

Angiographic delineation of the anatomy of pulmonary blood supply is of critical importance. Although it may be possible to accomplish this from a venous approach by crossing the VSD, the retrograde arterial approach is used most often because it allows easier access to surgically created shunts or systemic collateral vessels. A large-field radiographic format using biplane angiocardiography is advantageous in this situation. The image should provide a large field of view, ideally visualizing both lung fields simultaneously. Subtraction techniques have also proved useful in demonstrating the anatomy of interest.

Determining the presence or absence of a central pulmonary arterial confluence is of paramount importance. In addition,

Figure 42.4. Long-axis oblique view of left ventriculogram. Note single large VSD just inferior to aortic valve.

a detailed analysis of the systemic arterial collateral blood supply to the pulmonary arterial tree, which includes identification of the degree of intercommunication among the various vascular pathways, must be done. If a pulmonary artery confluence is present, the systemic-to-pulmonary collateral vessels may communicate directly with it or connect to it indirectly by a connection to a peripheral branch of the pulmonary artery. In addition, systemic collaterals may not communicate with central pulmonary arteries at all, instead terminating by connections to peripheral pulmonary artery branches that are separate from the confluence (noncommunicating) (29).

Angiographic evaluation should be tailored to the type of systemic-to-pulmonary collateral artery anatomy found in each patient. Historically, an initial aortogram was necessary to demonstrate the number and location of the systemic-to-pulmonary collateral arteries (Fig. 42.5). However, prior delineation of at least the origins of collateral vessels by echocardiography or other imaging studies allows one to proceed directly to selective injections in some cases. This avoids the larger-volume contrast injection used during nonselective aortography. Thus, nonselective injections now more frequently are performed later in a catheterization, if the pulmonary segmental arterial anatomy has not been defined completely by selective injections. The purpose of selective injections in the systemic-to-pulmonary collateral arteries usually is to delineate the extent of the pulmonary arterial tree supplied by each collateral vessel and to determine which type of pulmonary artery connection is present (Fig. 42.6). Such collateral injections can be enhanced by selective balloon occlusion techniques (40).

Both the central and the peripheral pulmonary arteries must be demonstrated. This allows detection of discrete stenoses or tubular hypoplasia involving the pulmonary arteries as well as the degree to which the central and peripheral pulmonary arteries communicate (41). Both the size and the peripheral distribution of the pulmonary arteries are important in planning the surgical treatment of these patients.

Figure 42.5. Aortogram demonstrates relatively large pulmonary confluence (arrow) but fails to define connections of individual, systemically derived collateral arteries.

Identifying communications between adjacent areas of the peripheral pulmonary arterial tree is particularly important and requires close attention to the sequential flow of contrast medium. Occasionally, an evanescent negative washout pattern can be appreciated that is due to a stream of unopacified blood from a connecting pulmonary artery flowing into an area of opacified pulmonary arterial tree. This may be the only indication of an existing communication (Fig. 42.6). If the initial echocardiogram or aortogram does not allow identification of a pulmonary artery confluence and selective injection of systemic-to-pulmonary collateral arteries fails to identify such a confluence, a retrograde pulmonary vein wedge injection may be helpful to identify hypoplastic central pulmonary arteries (Fig. 42.7).

Figure 42.6. Selective injection into a collateral artery arising from middle portion of descending thoracic aorta (same patient as in Fig. 42.5). Opacification of a pulmonary artery confluence by contrast medium indicates that a direct communication exists between the pulmonary artery confluence and the systemic collateral. Note stream of unopacified blood (arrow) washing out contrast medium in right pulmonary artery, an indication of competitive blood flow from a connecting vessel (see text).

Figure 42.7. Pulmonary vein wedge angiogram demonstrating a hypoplastic pulmonary artery confluence.

Some patients with complex patterns of pulmonary blood supply may require multiple injections of contrast material before the pulmonary vascular supply is documented. Because these patients often are hypoxemic and polycythemic, our policy is to inject a total dose of not more than 5 to 6 mL of contrast material per kilogram of body weight during any single procedure. This approach occasionally necessitates that the patient's diagnostic catheterization be divided into two sessions separated by at least 24 hours. Adequate hydration of these patients before, during, and after the study is mandatory to prevent thromboembolic complication or a potential complication secondary to hyperosmolality caused by the contrast material. Magnetic resonance imaging of sources of pulmonary blood can reduce the amount of contrast material needed at the time of angiographic examination (42).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the cyanotic infant includes TOF, transposition of the great arteries, tricuspid atresia, double-outlet RV with severe PS or PA, single ventricle with severe PS or PA, and total anomalous pulmonary venous connection with pulmonary venous obstruction. In the patient with PA-VSD in whom the pulmonary blood supply is normal or increased, the differential diagnosis includes lesions in which cyanosis is minimal and evidence of heart failure may be present. Such lesions include VSD, large PDA, atrioventricular septal defect, double-outlet RV or single ventricle without significant PS, persistent truncus arteriosus, and total anomalous pulmonary venous connection without pulmonary venous obstruction.

Physical examination often gives important clues to the correct diagnosis. When the physical examination is complemented by an electrocardiogram and chest radiograph, an accurate clinical diagnosis often can be established. Echocardiography is the noninvasive means to make an accurate diagnosis.

NATURAL HISTORY

The natural history of PA-VSD depends primarily on the adequacy of the pulmonary blood supply. Infants in whom a PDA is the primary source of pulmonary blood supply may become critically hypoxemic within the first few days of life as the PDA begins to close. In patients in whom the pulmonary blood

supply primarily is through systemic-to-pulmonary collaterals, the natural history can vary greatly because it depends on the adequacy of pulmonary blood supply by these channels. Most patients would have had an operation to increase pulmonary blood flow; however, some patients can reach adulthood without having undergone palliative surgery.

TREATMENT

Medical treatment for heart failure may be indicated for the rare patient with PA-VSD who has excessive pulmonary flow. Phlebotomy may occasionally offer relief from the side effects of extreme polycythemia in extremely hypoxemic patients. However, the treatment of the vast majority of PA-VSD patients is surgical.

It is critical to map the pulmonary artery architecture and sources of pulmonary blood supply. In addition, the degree of communication between the central pulmonary arteries and the major aortopulmonary collateral arteries (MAPCAs) must be determined preoperatively.

The goals of operation can be palliative for those patients whose pulmonary artery anatomy precludes complete repair. Depending on the clinical presentation, palliation can be accomplished by procedures designed to augment pulmonary arterial blood flow (systemic-pulmonary artery shunts, unifocalization) or by procedures designed to reduce pulmonary blood flow (interruption of unnecessary MAPCAs, unifocalization). In contrast, for patients whose pulmonary artery anatomy appears amenable to reconstruction, procedures leading to complete repair are indicated. Such procedures have included right ventricular outflow reconstruction for inducement of central pulmonary artery growth. This involves connecting the RV to the central pulmonary artery using a conduit. Such a connection can promote growth of the hypoplastic central pulmonary arteries so that they are adequate for complete repair (43). Unifocalization procedures involve disconnecting MAPCAs from their aortic origins, so that they can be positioned in the vicinity of the heart (or the central confluence) for final connection to the RV (Fig. 42.8). Connections between non-communicating segments are created, and a single source of flow is provided to the unifocalized lung. These unifocalizations are designed to incorporate the maximum number of pulmonary artery segments into the eventual right ventricular outflow reconstruction. The ultimate goal of such reconstructions is complete repair, defined as closure of all septal defects, interruption of all extracardiac sources of pulmonary arterial blood flow, and incorporation of at least 14 pulmonary arterial segments in a connection to the RV (44,45). Additionally, the central pulmonary artery size should be at least 50% of normal. At the end of operation, the right ventricular pressure should be $\leq 70\%$ that measured in the LV (some evidence suggests that pressure ratios of $< 60\%$ may offer a better long-term outlook). If higher, the VSD is fenestrated.

Historically, a staged reconstructive surgical approach was applied in patients who did not meet the criteria for complete repair at presentation (46). This involved lateral thoracotomies for “unifocalization” procedures to deal with significant arborization abnormalities of the pulmonary arteries and to create a single, central arterial source for each lung. If these operations were successful, the two reconstructed central pulmonary arteries were connected. Complete repair was performed at a later date.

Cho et al. (47) reported their experience with 495 patients treated with this approach. One hundred and sixty patients had preliminary surgical staging, including systemic-to-pulmonary artery shunts, right ventricular outflow reconstruction, and/or unifocalization procedures. Actuarial survival data are shown in

Figure 42.8. A: Preoperative aortogram. Note two large systemic-to-pulmonary collateral arteries, absence of a pulmonary artery confluence, and abnormal branching pattern of right pulmonary artery. B: Postoperative angiogram with an injection of contrast medium in right ventricular outflow tract demonstrates establishment of continuity between the branches of the right pulmonary arterial tree and creation of a pulmonary artery confluence.

Figure 42.9. The presence of MAPCAs was a significant factor associated with late mortality ($p = 0.0182$). Most of the patients (68%, $n = 335$) eventually underwent complete repair. Age at the time of complete repair ranged from 1 day to 54.6 years (mean, 11.3 years). Surgical mortality was 4.5%. Twenty-four patients had repair during the first year of life. There were two surgical deaths in this group (8.3%). At the end of the operation, the systolic pressure ratio between the RV and LV was 0.66 (SD = 0.180). The VSD was reopened in 22 patients who had excessively high right ventricular pressure (RV/LV systolic pressure > 0.85). Follow-up of 320 patients ranged from 1 month to 23 years (mean, 11.4 years). Fifty-two (16.3%) early survivors died during the follow-up period. Actuarial survival data are shown in Figure 42.10. The major predictor for late mortality was the need for reopening the VSD. Other investigators have reported similar results with the staged approach (48,49). We currently use this approach only in select patients.

Figure 42.9. Actuarial survival of patients who underwent palliative or reconstructive procedures, but had not yet undergone or were turned down for complete intracardiac repair. (From Cho JM, Puga FJ, Danielson GK, et al. Early and long-term results of the surgical treatment of tetralogy of Fallot with pulmonary atresia, with or without major aortopulmonary collateral arteries. *J Thorac Cardiovasc Surg* 2002;124:70–81, with permission.)

McElhinney et al. (50) and Reddy et al. (51,52) have proposed an alternative single-stage unifocalization/complete repair approach for previously unoperated patients with PA-VSD. Using a median sternotomy and cardiopulmonary bypass, both the right and left pulmonary arteries and MAP-CAs are unifocalized directly to the RVOT. A valved conduit is used to reconstruct the atretic RVOT. Malhorta and Hanley (53) have reported that a “complete” unifocalization could be accomplished in 76% of 464 patients managed in this way. Immediate closure of the VSD was possible in 56% of their patients. Over time, VSD closure was performed in 90% of the initial cohort (within 5 years of the midline, “single-stage” unifocalization). Overall surgical mortality for the series was 5.9%. The RV/LV systolic pressure ratio after VSD closure was <50% in over two-thirds of cases, and was stable during early follow-up (mean, 7 years). The earlier interventions inherent in this more aggressive approach may reduce the occurrence of segmental pulmonary vascular disease and progressive “loss”

Figure 42.10. Actuarial survival of patients who underwent complete repair in a single setting or after preliminary surgical stages. (From Cho JM, Puga FJ, Danielson GK, et al. Early and long-term results of the surgical treatment of tetralogy of Fallot with pulmonary atresia, with or without major aortopulmonary collateral arteries. *J Thorac Cardiovasc Surg* 2002;124:70–81, with permission.)

of segmental pulmonary arteries. However, longer duration of follow-up is needed to be certain of these benefits. Restenosis of both the reconstructed pulmonary arterial tree and the RV outflow conduit continue to pose late problems for these patients regardless of the initial surgical approach.

Our current approach at Mayo Clinic is similar favoring complete unifocalization via median sternotomy at 4 to 8 months of age in newly diagnosed patients. When an acceptable bilateral unifocalization can be achieved, the VSD is closed and right ventricular pressure is measured intraoperatively. An RV/LV ratio of >0.7 prompts VSD patch fenestration. In patients who require patch fenestration or in those who do not have VSD closure, the reconstructed RVOT allows pulsatile flow to the central pulmonary arteries as a stimulus for growth and catheter access for subsequent interventions in anticipation of eventual complete repair.

REPRODUCTIVE ISSUES

Patients with PA-VSD who become parents run a higher-than-normal risk that their children will have a congenital heart lesion. Women who have had correction and who have pulmonary artery pressures that are normal or only slightly increased should tolerate pregnancy well. For women in whom significant pulmonary artery hypertension persists after correction, pregnancy probably is not advisable. Likewise, in palliated patients who remain hypoxemic, pregnancy carries a risk to both the mother and the fetus (54).

Tetralogy of Fallot with Pulmonary Stenosis and Tetralogy of Fallot with Absent Pulmonary Valve

S. Lucy Roche ■ Steven C. Greenway ■ Andrew N. Redington

In many ways, tetralogy of Fallot (TOF) could be considered the archetype congenital heart disease (CHD); setting a pattern for the evolution of anatomical description, surgical management, pathophysiological understanding, and the appreciation of late outcomes in adult life. The origins of congenital cardiac surgery can be traced back to the early palliative procedures for TOF, and the triumph of efforts toward its surgical “correction” were quickly replicated in other conditions. Over the past 60 years, outcomes for patients with TOF have been transformed, so that now (assuming they have access to surgery) almost all infants born with TOF are expected to survive. Through the careful long-term study of these patients, TOF has become a model for late pathophysiology after CHD repair, and as we have learned more, our approach to surgical correction has adapted and changed. The late outcomes of patients with repaired TOF taught us the importance of providing lifelong follow-up for patients with CHD, and at the other end of the spectrum, TOF is leading the way in elucidating the genetic causes of CHD. In this chapter, we review not just the epidemiology, anatomy, and treatment of TOF, but its history. We hope to highlight just how much progress has been made and how the contributions of many have revolutionized outcomes for patients with this condition and developed our understanding of CHD as a whole.

EPIDEMIOLOGY

TOF is the commonest form of cyanotic CHD. A 2002 meta-analysis of the incidence of CHD, which included 41 studies pertaining to TOF, suggested that the best estimate of incidence would be 577 cases of TOF per million live births (1). The prevalence of TOF (number of patients living with the diagnosis at any given time) has significantly increased since the introduction of successful surgical repair. In the year 2000, the prevalence of TOF in the adult population of Quebec was $\approx 0.17/1,000$, and in Quebec’s children, the prevalence was $\approx 0.49/1,000$ (2). Consequently, it has been suggested that for many countries there are now numerically more adults with TOF than children.

TOF has a nearly equal sex distribution with perhaps a slight predominance in males. In a study that included information from 2.5 million live born infants and stillborn fetuses over a 10-year period, the Californian Birth Defects Monitoring Program reported a 1.1 relative risk of TOF in males compared to females (CI 0.9 to 1.3) (3). Maternal race seems to have little effect on incidence (4). Several studies have considered recurrence risk. Several studies have considered recurrence risk, both in siblings and offspring of the proband. A patient with TOF has approximately 2% to 3% chance of

having a sibling with CHD, although not necessarily TOF (5,6). Recurrence risk in the offspring of patients with TOF is undoubtedly affected by whether or not the proband has 22q.11.2 deletion. In the absence of 22q.11.2 deletion, prospective parents might expect 3% to 4% risk of having a child with CHD (5,7).

ETIOLOGY (GENETIC AND ENVIRONMENTAL FACTORS)

Although familial disease contributes only a small fraction to the overall incidence of TOF, its increased frequency in consanguineous populations (8) and markedly increased recurrence risk in some pedigrees (9) allude to a central role for genetics in the underlying etiology. While a chromosomal duplication or a microdeletion at the 22q11.2 locus occurs in approximately 20% of patients with TOF and single gene mutations have been identified in others, in at least 50% to 60% of patients with TOF the causal genetic influences remain unknown (Fig. 43.1). However, this is a rapidly advancing field and with advances in both genomics and our understanding of human cardiogenesis, this percentage is likely to decrease. The relatively large number of distinct genetic loci that have been associated with TOF highlights the complexity and apparent genetic heterogeneity of cardiovascular development.

TOF is found in two broad categories of patients: *syndromic* TOF, which occurs in the presence of additional noncardiac congenital anomalies and, the more common, *nonsyndromic* TOF, which occurs in apparent isolation, usually appearing sporadically in families with no history of CHD. Even within these two distinct classes, there is significant genetic overlap with mutations having been identified in the same gene in both syndromic and nonsyndromic patients (Fig. 43.2).

Syndromic Tetralogy of Fallot

To date, TOF is associated with 96 entries in the Online Mendelian Inheritance in Man (OMIM) database (<http://www.ncbi.nlm.nih.gov/omim>), and there are 32 listed syndromes that include the presence of TOF as a characteristic feature. Furthermore, there are many case reports and series of TOF in association with other syndromes in which the presence of a heart defect is more variable. The best known syndrome and most frequently identified cause of TOF occur as a result of a 22q11.2 microdeletion. This deletion has a prevalence of approximately 1 per 6,000 to 10,000 live births, with males

Figure 43.1. An illustration of the genetic causes of TOF.

and females equally affected (10–12), although frequencies as high as 1 per 3,000 to 1 in 6,000 live births have been cited in some populations (13). A hemizygous deletion of chromosome 22q11.2 or, rarely, point mutations within *TBX1* itself cause haploinsufficiency of the transcription factor *TBX1* and result in the 22q11.2 microdeletion syndrome also known as DiGeorge syndrome, the velocardiofacial syndrome, or by several other names (14–18). Today, the recommendation is that the syndrome be described using molecular terminology, that is, 22q11.2 microdeletion with the term DiGeorge syndrome reserved for those rare patients who have the clinical features but with no identified mutation (13).

The most common mutation at the 22q11.2 locus is a 3 megabase (Mb) deletion responsible for 90% of cases (19). Atypical deletions have also been described and increasing use of SNP arrays as an alternative to fluorescent in situ hybridization (FISH) for molecular diagnosis may enhance our knowledge regarding the frequency and effect of these atypical mutations (13). While most cases of 22q11.2 deletion arise sporadically as the result of de novo mutations, the inheritance of defects at this locus is autosomal dominant. Currently, 6% to 10% of new cases are familial, a percentage that is likely to increase due to the survival of individuals with previously lethal CHD (13). Since the phenotype is highly variable, even within families, it is not uncommon that genetic screening of a proband's family identifies the microdeletion in parents or siblings with mild or no clinical evidence of the disorder.

22q11.2 microdeletion syndrome is characterized by the presence of a conotruncal defect (TOF, pulmonary atresia with ventricular septal defect [VSD], persistent arterial trunk, interrupted aortic arch, isolated arch anomalies, and VSD), immunodeficiency, neonatal hypocalcemia, developmental or psychiatric abnormalities, facial dysmorphisms, and palatal defects (13). However, its precise features are highly variable. In a cohort of 251 patients with conotruncal lesions, a chromosome 22q11.2 deletion was found in 16% of TOF patients, 50% of patients with interrupted aortic arch type B, 35% of patients with persistent arterial trunk, and 33% of patients with an outlet (malalignment) VSD (20). The likelihood of finding a 22q11.2 deletion in the presence of a conotruncal defect is further increased by the presence of anomalies of the aortic arch (right-sided or high arch), subclavian artery, pulmonary artery (PA) (atresia, absent central confluence, absent pulmonary valve, or multiple aortopulmonary collateral arteries), or absence of the arterial duct (14,21). Interestingly, 22q11.2 deletion is very rarely found in association with other forms of CHD, such as transposition of the great arteries and hypoplastic left heart syndrome (10).

The next most common causes of syndromic TOF are those associated with major chromosomal abnormalities including Down syndrome (Trisomy 21), Edward syndrome (Trisomy 18),

Figure 43.2. Genetic mutations identified in patients with syndromic and nonsyndromic TOF.

and Patau syndrome (Trisomy 13). These trisomies are estimated to cause 5% to 7% of syndromic TOF with Trisomy 21 responsible for most cases (22).

Smaller deletions and duplications have also been described as causes of syndromic TOF. These copy number variants (CNVs) are larger than 1,000 base pairs but are submicroscopic and, therefore, not detected on a routine karyotype. The importance of these rare variants in human disease has recently been appreciated due to technologic advances allowing genome-wide surveys at greater resolution than previously possible. These CNVs identify known or candidate TOF disease genes (23,24). At the current time, these CNVs account for only a small fraction of syndromic TOF but, with increasing use of microarrays and high-throughput DNA sequencing, we can expect to identify genetic abnormalities in a larger proportion of TOF patients. Microarray testing for CNVs in the population of syndromic TOF patients may have a relatively high yield since approximately 25% of patients with syndromic CHD have an identifiable mutation (24,25).

Single gene causes of syndromic TOF have been described and include mutations in *TBX5* causing Holt-Oram syndrome, which manifests most commonly as forearm and thumb anomalies with atrial septal defect (26). Mutations in *JAG1* and *NOTCH2* cause Alagille syndrome, a disorder characterized by cholestasis, CHD, skeletal and ocular anomalies, and characteristic dysmorphic features (27–29).

Nonsyndromic Tetralogy of Fallot

Mutations in many genes have been linked with nonsyndromic TOF (Fig. 43.2). In some cases, gene discovery in syndromic patients has been helpful in identifying the cause of nonsyndromic TOF. For example, 22q11.2 deletion may be present in up to 6% of patients with nonsyndromic TOF and appears more frequently in those with pulmonary atresia (30). In addition, mutations in *JAG1*, initially identified in Alagille syndrome, have been found in patients with isolated TOF (31–34), and mutations causing nonsyndromic TOF have also been identified in *TBX1*, which is deleted in the 22q11.2 microdeletion syndrome (22,31). Few studies of nonsyndromic TOF have considered inheritance; in those that have, mutations were inherited from phenotypically normal parents. This observation suggests reduced penetrance and/or the presence of additional cofactors and has led to the proposal that nonsyndromic TOF may fit a “multiple-hit” model of etiology (5,35). A variety of environmental exposures have been identified that contribute a modest increased risk for TOF or other conotruncal defects and include maternal pregestational diabetes, febrile or viral illnesses, vitamin A exposure, and exposure to organic solvents (36). Perhaps the development

of nonsyndromic TOF requires both genetic susceptibility and one or more environmental insults. However, to date, evidence supporting this hypothesis remains weak and anecdotal.

The contribution of CNVs to nonsyndromic TOF has also been examined (33,37). Similar to the loci identified in syndromic TOF, these CNVs identify known and putative TOF disease genes. Of the 12 CNVs identified, there were only three loci affecting known disease genes (*JAG1*, *NOTCH1*, and *TBX1*). Furthermore, several of these loci affected regions of DNA that did not contain any known genes, suggesting that mutations in non-protein coding DNA may contribute to the development of disease. The most common CNV affected the 1q21.1 locus, which accounted for 1% of TOF cases in this study (33). This locus has been identified by other groups and has been associated with psychiatric and neurologic disease as well as TOF and other CHD (38–47). This potential link between “nonstructural” nervous system disease and TOF is certainly intriguing since it parallels the findings for the 22q11.2 deletion and syndromic TOF.

To date, mutations in 12 single genes have been associated with nonsyndromic TOF but, thus far, each mutation appears to contribute to only a tiny percentage of cases. The disease genes identified primarily consist of transcription factors (*NKX2.5* [48,49], *GATA4* [50–52], *ZFPM2* [53,54], *GATA6* [55,56], *TBX1* [22,57], and *TBX20* [58]) and receptors or ligands in the NOTCH (*NOTCH1* [59] and *JAG1* [22,32]) or NODAL (*FOXH1* [60], *TDGF1* [60], *GDF1* [61], and *CFC1* [60]) pathways.

Current and Future Roles of Genetic Testing and Counseling in Tetralogy of Fallot

The potential genetic links and implications of genetic testing in TOF should be discussed with the parents of each newly diagnosed patient, whether a diagnosis of TOF has been made in a fetus or postnatally. There is also a role for genetic counseling in older patients, who may have been diagnosed with TOF at a time before much was known about its potential genetic etiology. In each case, the patient or parents should decide whether or not genetic testing is appropriate after considering the potential benefits and disadvantages. When combined with adequate resources for counseling, genetic testing can provide useful information for physicians, the parents of children with TOF, and the patients themselves.

For physicians, genetic testing of patients with TOF may identify a syndrome associated with other abnormalities that should be considered when planning management and discussing prognosis. For instance, there are potentially important reasons to identify a 22q11.2 deletion in infants with TOF before they undergo cardiac surgery (62). First, at the time of surgery and during the postoperative period, it is useful to anticipate and correct hypocalcemia, which can result as a consequence of the hypoparathyroidism seen in over 50% of patients with 22q11.2 deletion (63). Second, a small percentage of infants with 22q11.2 deletion exhibit complete T-cell deficiency, a condition known as “complete DiGeorge syndrome.” Such patients are at risk of iatrogenic graft-versus-host disease (GVHD), which may occur due to transfusion of lymphocyte-containing blood components and is a potentially fatal, but preventable, complication (64). Transfusion-associated GVHD is usually only a risk if CD4 and CD8 T-cell counts are below 1,000 and 800 cells/mm³, respectively (65). Guidelines suggest that infants with known or suspected 22q11.2 deletion should receive irradiated blood products at the time of cardiac surgery unless T-cell lymphocyte deficiency has been specifically excluded (66).

For the parents of a child with TOF, and for the patients themselves, another possible benefit of genetic counseling and testing is the provision of information that might inform future reproductive decisions. In addition, genetic testing may iden-

tify a condition that is associated with learning difficulties. In such cases, obtaining a genetic diagnosis may help the family of a patient with TOF obtain additional educational support from an early age. As they age, patients with 22q11.2 microdeletion remain at risk of symptomatic hypocalcemia and may also develop psychiatric disorders that would benefit from early recognition and treatment (67).

Recommendations for genetic testing in TOF and other forms of CHD have been developed (21). Currently, these guidelines advocate genetic testing only in children with syndromic TOF (21). However, many centers have already adopted routine genetic screening for all patients with TOF. Although routine clinical genetic testing is currently limited to the detection of large chromosomal abnormalities either through karyotyping or through FISH, advances in technology and decreasing costs in DNA sequencing may lead to an increased prevalence of this approach together with improved diagnostic yields. Furthermore, approximately 6% to 10% of children with a 22q11.2 deletion will have no other features of the disorder and will be missed if screening is confined to those only with obvious external abnormalities.

ANATOMY (MORPHOLOGIC, ECHOCARDIOGRAPHIC, AND ANGIOGRAPHIC CORRELATIONS)

The journey towards anatomic understanding of this complex heart defect began well before the time of Etienne-Louis Arthur Fallot and continues to this day. In his 1888 papers concerning “la maladie bleue,” Fallot acknowledged earlier reports of patients with the same pathology, including the paper by Danish anatomist and Bishop, Niels Stenson, which is considered to be the earliest description (68). In 1671, Stenson reported his pathologic findings in a fetus with multiple abnormalities, including cardiac features we would now recognize as TOF (69). One hundred years later, Eduard Sandifort, an anatomist at the University of Leiden, published the first clinical-anatomical correlate of this condition when he described the life and subsequent autopsy findings of a 12-year-old boy who had suffered from progressive cyanosis and breathlessness despite being “perfectly normal at birth” (70). Detailed anatomical diagrams accompanied his report and, unlike others present at the autopsy, Sandifort realized that the condition must have been congenital (70). In the 1800s, there were other reports including 15 cases published in John Farre’s textbook on cardiac malformations (71) and 64 cases referenced by Thomas Bevil Peacock (72). Fallot’s important contribution was to clearly define the clustering of four distinct anatomical features as a frequent cause of cardiac cyanosis and to introduce the term “tetralogy.” This defining contribution was forever acknowledged when Maude Abbott gave the disease its eponym. Fallot also dispelled the widely held belief that the blue discoloration of these patients was due to patency of the oval fossa (73). Fallot’s tetralogy, as described by him, is: stenosis of the PA, a VSD, hypertrophy of the right ventricle (RV), and rightwards deviation of the origin of the aorta (68); and, for over 120 years, generations of medical students have memorized these cardinal features.

More recently, increasing knowledge of embryonic growth, understanding of cardiac morphology, and the development of rigorous nomenclature systems have resulted in a search for the pathognomonic features unique to a diagnosis of TOF. In today’s perception, TOF is generally considered a “monology” from which all four characteristic features result. The two great schools of cardiac morphology have somewhat different perspectives on this matter but the areas of controversy are relatively minor. In Anderson’s view, the characteristic abnormalities of TOF occur because the components that normally unite to form the outlet of the RV remain separate during development. He maintains

Figure 43.3. Parasternal short axis view of an infant with TOF demonstrating: (1) anterior and cephalad deviation of the outlet septum, (2) the VSD, and (3) narrowing of the subpulmonary RV outflow tract.

that the defining morphology is anterior-cephalad deviation of the outlet (infundibular) septum (which may sometimes be only a fibrous remnant) relative to the septomarginal trabeculation (SMT) together with malformation of the SMTs (74,75). In contrast, the Van Praags judge underdevelopment of the subpulmonary infundibulum to be the primary pathology; with all characteristics of TOF (including anterior-cephalad deviation of the outlet septum) being sequelae of this one pathologic feature (76,77). Whichever abnormality ultimately proves to be defining, anterior-cephalad deviation of the outlet septum (which is a much larger structure in TOF than in the normal heart) is certainly a cardinal feature. Since deviation of the outlet septum is often easily appreciated by echocardiography, identification of this anatomy is key to diagnosis (Fig. 43.3).

The most frequent segmental anatomy in patients with TOF is normal abdominal situs with the heart located in the left chest, its apex pointing to the left (levocardia) and usual atrial arrangement with concordant atrioventricular and ventriculoarterial connections. By contrast, the intracardiac anatomy is highly variable (78) and surgical planning for individual patients is facilitated by establishing the precise configuration of each of the cardinal anatomical components. Furthermore, it should be emphasized that TOF may coexist with other connections (e.g., double outlet RV) and indeed may be the underlying diagnosis even when there is complete atresia of the right ventricular outflow tract (RVOT) with or without the presence of major aortopulmonary collateral arteries.

The Interventricular Communication

The large, unrestrictive interventricular communication of TOF is always “roofed” by the aortic valve (Fig. 43.4) but its remaining borders are somewhat variable and complicated to define since they depend on the tissue planes considered. In general, the defect is described from its RV aspect (which is the aspect the surgeon encounters when closing it). The crest of the ventricular septum usually terminates with the

Figure 43.4. Typical parasternal long axis view in a patient with TOF. The aorta overrides the crest of the ventricular septum. VSD, ventricular septal defect; LV, left ventricle; RV, Right ventricle; LA, left atrium.

Y-shaped division of the anterior and posterior limbs of the SMT. In approximately one-fifth of Caucasian patients, a muscular rim, formed by the limbs of the SMT, the ventriculo-infundibular fold (VIF) and the muscular outlet septum, encircles the RV side of the VSD posteroinferiorly and thus protects the conduction axis from damage (74). More commonly, the VIF fails to reach the SMT and an area of fibrous continuity exists between the aortic cusps and the septal leaflet of the tricuspid valve to form the posteroinferior margin of the defect. In these cases, the defect incorporates a remnant of the membranous septum and is perimembranous (74). Its superior margin is usually formed by the deviated muscular outlet (or infundibular) septum. In some patients, there is absence, or near absence, of the infundibular septum, and the cusps of the aortic and pulmonary valves are in fibrous continuity and together form the superior border of the VSD. In these cases, the VSD is described as both doubly committed and subarterial, and while usually there is a muscular posteroinferior rim, the defect may also be perimembranous. This variant

Figure 43.5. Subcostal right oblique section of TOF with a doubly committed VSD. The arrow points to point of fibrous continuity between the leaflets of the aortic valve and the hypoplastic pulmonary valve. RV, Right ventricle; Ao, Aorta; PT, Pulmonary trunk.

is rare in some populations, but relatively frequent in those of South American or South-East Asian descent (Fig. 43.5). In the past, it was argued that such patients should not be classified as having TOF since they have no muscular infundibular septum. It has been argued, however, that the outlet septum is present, albeit in the form of a fibrous remnant or raphe (79) and, since postnatally these patients exhibit all four classical features, this entity is now accepted to be a variant of TOF (75,80). TOF with a doubly committed VSD may be diagnosed preoperatively by echocardiography or angiography (79,81). Compared to the majority of patients with TOF, those with a doubly committed VSD are at higher risk for the development of aortic regurgitation, both before and after repair, and have a higher incidence of residual postoperative RVOT obstruction (RVOTO) (82).

The large outlet VSD seen in TOF can extend into the inlet component of the ventricle, either with or without an associated common atrioventricular valve, and there may be additional muscular VSDs that can be difficult to image by echocardiography because of the equalization of RV and left ventricle (LV) pressures. In each case, effort should be made to exclude additional muscular defects by imaging the ventricular septum with reduced Doppler color scale.

Aortic Position

In TOF, if an imaginary line were drawn perpendicular to the long axis of the heart, upwards from the crest of the ventricular septum, it would transect the cusps of the closed aortic valve and, when the valve opened, this line would extend

onwards into the aortic root. This is what is meant by the term “overriding aorta.” In patients with TOF, the aorta overrides the VSD, a relationship best appreciated by echocardiography from the parasternal long-axis view (Fig. 43.4). The degree of aortic override varies significantly between 15% and 95% (83), a feature which has created some confusion. Contention remains as to whether or not hearts in which there is >50% aortic override should be classified as double outlet RV, irrespective as to whether there is a bilateral infundibulum. The precise mechanics underlying aortic override in TOF remain incompletely understood. However, most authorities agree that, compared to normal, there is rightwards malposition and clockwise rotation of the aortic root (76,77,84–86).

Right Ventricular Outflow Tract Obstruction

Multilevel obstruction to pulmonary blood flow is a hallmark of TOF although the severity of obstruction varies considerably from patient to patient (Fig. 43.6). In TOF, the length of the infundibular region is similar to that of normal hearts (76,84), but its diameter is usually significantly reduced. Whether this reduction in diameter is primarily due to developmental hypoplasia (76,77) or is caused by anterior cephalad deviation of the outlet septum combined with hypertrophy of the SMTs (74) remains of academic interest but, from the patients' perspective, it is the effect of this narrowing that is important. The degree of narrowing of the subpulmonary infundibulum is variable in extent and timing. Progression from a patent RVOT to atresia during fetal life is well described, resulting in TOF with PA (also termed pulmonary

Figure 43.6. There is potential for multilevel obstruction of the RV outflow tract. This can occur because of (1) subpulmonary infundibular obstruction, (2) valvular pulmonary stenosis, and (3) branch PA stenosis. The RVOT is best imaged in a parasternal short axis view. Color flow Doppler can be used to demonstrate both the location and severity of obstruction.

atresia with VSD) (87) and, postnatally, the development of increasing obstruction leading to symptomatic cyanosis is commonplace. The typical pulmonary valve in TOF is thickened and obstructive, and is frequently bicuspid. The main PA and its branches exhibit highly variable anatomy with important abnormalities in up to 40% of patients (88,89). The high incidence of discrete stenosis at the origin of the left PA is related to constriction of a sling of ductal tissue at the site of its insertion (88).

Coronary Arteries

The prevalence of coronary artery abnormalities in TOF varies somewhat between surgical, pathologic, and angiographic series but is approximately 5% to 7% (90). The significance lies mainly in an increased vulnerability of the anomalous vessels to injury during surgical repair, particularly if they cross the RVOT (91–93). In approximately 4% of TOF patients, the left anterior descending artery (LAD), or an accessory LAD, takes origin from the right coronary artery (RCA) or right coronary sinus and crosses the RVOT in its course towards the LV (90). A single coronary artery (more often from the left coronary sinus) is the second most frequent variant and occurs in ≈1% of patients (90). The solitary artery usually divides early into left and right branches, one of which may pass behind or in front of the RVOT. When a single coronary arises from the left sinus, it is the right branch that lies in a vulnerable position, whereas when the single coronary arises from the right sinus, it is the left branch that is vulnerable (94). In patients with significant RV hypertrophy, there may be enlargement of the infundibular (or conal) branch of the RCA. Strictly speaking, this is not anomalous anatomy but, since this branch supplies the musculature of the subpulmonary infundibulum, its prominence may nonetheless challenge the surgeon.

In previous eras, when ventriculotomy and transannular patching were frequent components of TOF repair, the risk of transecting an anomalous coronary vessel was high and patients with abnormal coronary anatomy had increased operative mortality. Preoperative coronary angiography became routine and, if anomalies were suspected, corrective surgery was delayed until midchildhood by use of a palliative shunt procedure (93). Today, there are several surgical techniques for dealing with anomalous coronaries in patients with TOF and it is rarely necessary to delay surgery, even for abnormalities that might previously have precluded repair. For the majority of patients who have a reasonably sized pulmonary valve annulus, the now standard transatrial-transpulmonary approach (see below) can be used successfully, even in the presence of coronary artery anomalies (95). Several options exist for infants who have both a coronary artery that crosses the RVOT and severe pulmonary annulus hypoplasia. These include RVOT reconstruction with single or separated patches (96,97), placement of an RV-to-PA conduit (96), and use of a native PA flap to protect the anomalous coronary by placing a glutaraldehyde-treated patch between a low ventriculotomy and the PA (98). The technique employed usually depends on surgical preference. It is not always possible to directly identify anomalous coronaries at the time of surgery, so it is important that the coronary anatomy be delineated by careful preoperative echocardiography.

Aortic Arch

In 20% to 25% of patients with TOF, the aortic arch is right-sided with mirror image branching (i.e., it crosses over the right main bronchus and the first branch is a left-sided brachiocephalic artery, which divides into the left subclavian and left carotid arteries [76,99,100]). In isolation, a right-sided aortic

arch in TOF causes no additional symptoms, since it does not produce a complete vascular ring. A right-sided aortic arch may be diagnosed on plain chest x-ray by the absence of the expected left-sided aortic knuckle. By echocardiogram, a right aortic arch is best diagnosed from the suprasternal notch. The standard suprasternal view (in which the scanning plane extends from the right nipple to left scapula with the probe's marker directed towards the patient's back) will demonstrate only part of a right aortic arch (101). To obtain a full arch image, the transducer must be rotated clockwise from the standard position, so that the marker faces away from the patient and the plane of ultrasound extends from the left border of the sternum to an area just right of the spine (101). From this position, the first branch of a right aortic arch can be traced coursing leftward (in contrast to a left aortic arch where this vessel would course rightwards before bifurcating). A right-sided aortic arch may also be diagnosed by fetal echocardiography, when, in a transverse view, the "sausage-shaped" arch is located to the right of the trachea, rather than its usual left-sided position (102).

Aortopulmonary Collaterals

Collateral vessels from the aorta to the pulmonary arteries are unusual in TOF in the absence of pulmonary atresia but approximately 6% of patients have a patent arterial duct (88,89).

Other Associated Cardiac Abnormalities

Important variants of TOF exist and the different anatomy may impact differently on the patient's physiology, clinical presentation, and surgical management.

Tetralogy of Fallot with Pulmonary Atresia

Morphologically, many clinicians (including the authors of this chapter) consider the combination of a VSD with aortic override and pulmonary atresia, to be part of the spectrum of TOF, albeit with the most extreme form of RVOT. Others believe this condition to be a separate entity. Regardless of the formal classification, this variant has such marked variability in pulmonary blood supply, clinical presentation, and surgical management strategies that it warrants special consideration. In this textbook, this entity is described in detail in the Chapter 42 titled "Pulmonary Atresia and Ventricular Septal Defect," and is not discussed further here.

Tetralogy of Fallot with Origin of One Pulmonary Artery from the Right Ventricle and One from the Ascending Aorta

In this rare variant, there is discontinuity of the branch pulmonary arteries with one PA (more often the left) originating from the ascending aorta (103–107). Although use of the term is generally discouraged (because it is teleologically incorrect), this anatomy is sometimes known as a "hemitruncus." It is important to identify patients with this abnormality (which may be overlooked initially) and undertake surgical repair early, so as to prevent the development of left lung pulmonary arterial hypertension.

Occasionally, there may be apparent complete absence of the left PA in the setting of TOF (108–110), although such cases (particularly if recognized in early infancy) should be investigated for possible origin of the left PA from a left-sided arterial duct (commonly arising from the base of the left brachiocephalic or subclavian artery), as this can sometimes be probed, dilated, stented, and rehabilitated, even after complete closure of the duct.

Figure 43.7. MRI of infant with TOF with absent pulmonary valve. Note the massive dilatation of main and branch pulmonary arteries. RV, Right ventricle; PT, Pulmonary trunk; LPA, Left pulmonary artery; RPA, Right pulmonary artery. (Images courtesy of Dr. Shi-Joon Yoo at The Hospital for Sick Children, Toronto.)

Tetralogy of Fallot with Absence of the Pulmonary Valve Leaflets

In approximately 3% to 6% of patients with TOF, the pulmonary valve leaflets are absent (78,100) or only a rudimentary ridge of tissue is present. This variant is associated with significantly aneurysmal main and branch pulmonary arteries that may compromise the airways and respiratory function (Fig. 43.7). The first description of this anomaly is attributed to Chevers (111) in 1847 and the first detailed case report was published in 1927 by Kurtz et al. (112) who described the clinical features and postmortem findings of an 11-year-old boy. Despite an absence of pulmonary valve tissue, these patients usually exhibit some degree of RVOTO. This is almost always caused predominantly by a ring of tissue present at the level where the pulmonary valve leaflets would be expected, rather than by infundibular stenosis (113,114). An anatomical peculiarity of TOF with absent pulmonary valve is that the arterial duct is nearly always absent (113,115). In about 50% of patients with TOF and absent pulmonary valve, there is also a right-sided aortic arch, and the condition may also be associated with absent or aortic origin of a branch PA.

Discussion continues as to whether the massive PA dilation already present by the time of birth is primarily attributable to an abnormality of pulmonary vessel tissue, the orientation of the subpulmonary infundibulum, or severe in utero pulmonary regurgitation (PR) (consequent to absence of the arterial duct and pulmonary valve leaflets) (Fouron, 1990:829). Free PR makes the aneurysmal pulmonary arteries highly pulsatile and they often cause external compression of the airways, sometimes completely obliterating the bronchial lumens during systole. This leads to varying degrees of tracheobronchial malacia and air trapping. Rabinovitch et al. (116) described abnormal branching of the pulmonary arteries with “tufts” of arteries that entwined and compressed the intrapulmonary bronchi on autopsy of two patients with TOF and absent pulmonary valve. The authors suggested that their findings might explain why some patients continue to experience respiratory

problems, despite relief of compression of the main stem bronchus by surgical repair (114).

On examination, newborns with TOF and absent pulmonary valve exhibit “to-and-fro” systolic and diastolic murmurs and a single second heart sound, whereas patients with isolated TOF rarely have a diastolic murmur. Most are initially cyanotic, but this usually becomes less apparent during the first week of life (114). Around 40% of patients have some degree of respiratory distress at birth (113). Since there is usually less RVOTO than in other forms of TOF, as pulmonary vascular resistance falls, infants usually develop signs of increased pulmonary blood flow. The chest x-ray of these patients is distinctive and is characterized by a moderately enlarged cardiac silhouette that has a prominent bulge at the upper left cardiac border, caused by the massively dilated proximal pulmonary arteries, and usually normal peripheral vascular markings. Some infants also demonstrate lobar emphysema (117). MRI or CT scanning may add further information about the extent and severity of airway disease (118).

The clinical course and prognosis of patients with TOF and absent pulmonary valve is variable. Although there is probably a spectrum of disease, general consensus divides patients into two groups: those who exhibit severe respiratory problems in early in life and those who do not. Patients who present with severe respiratory compromise immediately after birth or in the first weeks of life will generally require urgent intervention and have a worse outcome than those who escape early intervention with relatively minor respiratory involvement. For severely affected infants, some clinical improvement may be gained by prone positioning, which allows the pulmonary arteries to fall forward and away from the bronchi. Otherwise, these patients usually require prompt intubation and positive airway pressure ventilation to maintain their airway. It is clear from early surgical series that infants who present with severe respiratory distress and require preoperative ventilation have the highest surgical mortality (119). However, modern surgical strategies and improvements in intensive care management may have improved outcomes in this group. The authors of a 2007 publication reported successful weaning

from ventilation and survival to eventual hospital discharge in all 61 consecutive neonates with TOF and absent pulmonary valve surgically repaired in the preceding 12 years (120).

Several surgical options have been suggested for management of TOF with absent pulmonary valve and, to date, no clear consensus exists as to which is best. Strategies usually focus on intracardiac TOF repair in conjunction with plication and reduction of the pulmonary arteries where necessary. The pulmonary arteries can be reduced by removal of tissue from either their anterior or posterior walls. Some surgeons also suspend the left PA to the anterior chest wall on closing the chest, hoping to further release pressure on the bronchi (119,120). An alternative is to perform the LeCompte maneuver, that is, transect the ascending aorta during repair and move the right PA anterior to it, away from the tracheobronchial tree (121). The surgeon must also decide whether or not to implant a pulmonary valve at the time of the primary procedure, which usually requires placement of a valved RV-to-PA conduit. Some groups also advocate stenting the airway at the time of surgical repair. However, there is no clear consensus about the best approach (122). Even after complete surgical repair with apparent relief of airway obstruction, patients may suffer long-term problems such as recurrent respiratory tract infection, wheezing, and reactive airways disease; some require reintervention for such symptoms (119).

Tetralogy of Fallot with an Atrioventricular Septal Defect

Around 2% of patients with TOF also have an associated atrioventricular septal defect (AVSD) (123). These patients usually present more like patients with isolated TOF than they do like patients with isolated AVSD, since the RVOT limits pulmonary overcirculation and prevents symptoms of heart failure. Furthermore, they will often have left axis deviation on the electrocardiogram. The association should be actively excluded in children with Down syndrome and apparently isolated TOF. It is important to remember in this regard that a primum component may not always be present in such cases, and the presence of an associated AVSD may only be indicated by the presence of a trifoliate ("cleft") left atrioventricular valve component of a divided common atrioventricular junction (which should be repaired at the time of correction, to avoid later valvar regurgitation). The restriction to pulmonary blood flow protects the pulmonary arteries, and these patients can usually be repaired somewhat later than those with an isolated AVSD. Since surgical repair involves division of the inlet valve as well as closure of the interatrial and interventricular septal defects and reconstruction of the RVOT, this combination of cardiac defects is a particular surgical challenge. Nonetheless, it has been shown that primary repair of both the AVSD and TOF may be performed in the first few months of life and produces better outcomes than an initial palliative approach with full repair delayed until 4 to 6 years of age (123).

CLINICAL FEATURES AND INVESTIGATION

Prenatal Diagnosis

Advances in fetal echocardiography, the development of structured screening programs, and increasing sonographer experience have resulted in increased prenatal diagnosis of CHD, including TOF and its variants (124,125). In expert hands, the prenatal diagnosis rate for TOF may be as high as 70% and the diagnostic accuracy can be as high as 90% (124,126). The main source of diagnostic inaccuracy results from diagnosing TOF with pulmonary stenosis in fetuses that are then postnatally found to have TOF with pulmonary atresia (124,126).

To some extent, this may be unavoidable since there is good evidence that the outflow tract obstruction seen in TOF may be progressive during fetal life and that some fetuses with patent pulmonary valves early in pregnancy will have developed complete pulmonary atresia by the time of birth (87,127). In 2008, Kaguelidou et al. (128) examined outcomes for 238 fetuses diagnosed with either TOF ($n = 153$) or TOF with pulmonary atresia ($n = 65$). The median gestational age at diagnosis was 24 weeks, with 45% of cases diagnosed before 24 weeks. Ultrasonography detected coexisting extracardiac anomalies in 70/153 fetuses with TOF. Fetal karyotyping results were available in 132/153 TOF cases and 106/153 fetuses were screened for a 22q11.2 deletion. Of those screened, Trisomy 21 was diagnosed in 4.5%, Trisomy 13 in 0.8%, and other rare (often sex chromosomal) abnormalities in 6%. A 22q11.2 deletion was found in 15% of the 106 fetuses with TOF that were screened. As a result of the antenatal screening, 24% of parents with fetus diagnosed with TOF decided to terminate their pregnancy (a lower proportion than in cases where the diagnosis was TOF with pulmonary atresia). The authors reported that the presence of associated chromosomal abnormalities or severe extracardiac abnormalities were factors that determined parental choice (128).

Postnatal Presentation and Natural History

The clinical signs and symptoms seen in infants born with TOF generally vary in accordance with the degree of RVOTO and frequently the diagnosis will be made following neonatal detection of an asymptomatic murmur. Infants with the most severe obstruction shunt right-to-left across the VSD and have reduced pulmonary blood flow. They often present with cyanosis in the first days of life. Cyanosis may be recognized at the time of delivery, during routine measurement of newborn oxygen saturation or perhaps only during episodes of crying. Infants with minimal RVOTO usually have a normal, or near normal, oxygen saturation after birth. These babies ("pink tets") may present with heart failure symptoms (poor feeding, tachypnea, diaphoresis, and failure to thrive) at 4 to 6 weeks of age due to increasing pulmonary blood flow as their pulmonary vascular resistance drops and they shunt left-to-right across the VSD.

Typical auscultatory findings in a newborn with TOF include a normal first heart sound, a single second heart sound, and a loud systolic ejection murmur most clearly audible at the left lower sternal border that radiates to the back. This murmur originates from turbulent blood flow across the narrowed RVOT and not from blood flow across the large nonrestrictive VSD, which produces equalization of ventricular pressures. Generally speaking, the loudness of the murmur is proportional to, and the length of the murmur inversely proportional to, the degree of RVOTO (i.e., a loud short murmur indicates significant RVOTO). However, in those patients with severe RVOTO or who are actively spelling, the murmur may be both short and soft or virtually inaudible.

Fallot's three patients died at the ages of 19, 26, and 36 years; interestingly not from their CHD but of tuberculosis (68). At the time, adult survivors of TOF would have been unusual since, without surgical intervention, the outcome from TOF is poor. There are two retrospective studies that considered autopsy data from fixed geographical populations during time periods prior to the availability of any cardiac surgery and, as such, describe the natural history of TOF. The first, conducted in Denmark, found that without surgical intervention only 66% of babies born with TOF survived to 1 year of age, 49% until 3 years of age, and only 24% lived to the age of 10 years (129). Similar statistics were seen in the population of Central Bohemia where 64% survived the first year of life

but only 14% of children with unpalliated or unrepaired TOF survived beyond 15 years of age (130).

Not only is the mortality from untreated TOF high but the child's quality of life is also poor and the distress caused to families great. Although two-thirds of newborns with TOF are acyanotic and appear healthy at birth, by 6 months of age over half will have become desaturated at rest (131). This clinical progression occurs because of worsening infundibular stenosis and RV hypertrophy, which further reduces pulmonary blood flow and increases right-to-left shunting across the VSD. Intermittent hypercyanotic episodes ("tet spells") are one of the defining features of TOF, now seen less frequently due to earlier recognition and intervention. During hypercyanotic spells, which are often provoked by crying but then associated with a quite different frantic cry during the episode that is probably due to the pain of skeletal muscle and myocardial ischemia, the patient develops abruptly worsening cyanosis and breathlessness that may ultimately lead to loss of consciousness and, in severe untreated cases, death. In milder cases, postspell somnolence is characteristic. The mechanism for cyanotic spells remains unknown but the previous assumption that they were related to "infundibular spasm" is difficult to reconcile with the lack of a "sphincter" function of the subpulmonary infundibulum and the frequent recognition of identical clinical features in those lacking a subpulmonary infundibulum (e.g., tetralogy with a doubly committed VSD). Rather, the physiology is more likely related to acute changes in inotropy (endogenous catecholamine release in response to pain), increased systemic oxygen consumption (secondary to pain and anxiety) leading to reduced mixed venous oxygen content, acute reduction in systemic vascular resistance (they are more frequent during febrile illness), and with decreased RV preload associated with tachycardia (they can be induced by atrial tachycardias), and this understanding underpins their treatment (see below).

ECG Findings

Preoperatively, the electrocardiogram in TOF characteristically shows sinus rhythm with normal or rightward axis deviation and right ventricular hypertrophy. As previously mentioned, there may be left axis deviation in TOF associated with AVSD. Surgical repair of TOF often disrupts the electrical conduction pathways and afterwards >90% of patients exhibit right bundle branch block (RBBB) (Fig. 43.8) (132–135), although this has become less marked with the transatrial and transpulmonary repair. As discussed below, in patients left with residual PR, the QRS duration (QRSd) tends to increase over time and may have prognostic implications (136,137).

Chest X-Ray Findings

The typical chest radiograph findings in TOF are well known and consist of a normal cardiac size but with an abnormal morphology characterized by an upturned apex ("boot-shaped" heart) related to RV hypertrophy, deficiency of the main PA segment ("PA bay" visualized as a notch in the upper left cardiac border), and reduced pulmonary vascularity (138). However, historically, an upturned apex was only actually present in two-thirds of cases and a more consistent sign of RV hypertrophy was said to be increased proximity of the anterior cardiac border to the sternum on a lateral film (139). Today, since most patients are operated during infancy and before they develop significant RV hypertrophy, the typical "boot-shaped heart" is much less commonly seen. It is usually possible to diagnose a right-sided aortic arch from the chest x-ray by absence of the usual left-sided aortic knuckle, a bulge to the right of the upper mediastinum, and an impression to the right of the trachea (139).

Echocardiography

Echocardiography is one of the most important tools in the diagnosis and follow-up of patients with TOF. Obtaining images of intracardiac anatomy, as described above, can make the diagnosis of TOF and it is important to specifically check for associated abnormalities. Echocardiography (either epicardial or transesophageal) also plays a role at the time of corrective surgery, particularly in checking the completeness of VSD closure and relief of RVOTO. During the immediate postoperative phase, echocardiography is routinely used to assess LV and RV function, atrioventricular valve function, and the status of the RVOT. Its role in postoperative follow-up is primarily in the surveillance for late complications, particularly in patients with important PR (see the following section).

Angiography and Magnetic Resonance Imaging

Preoperative cardiac catheterization and invasive angiography for TOF have been almost entirely supplanted by other imaging modalities, most commonly echocardiography. In rare circumstances, angiography may still be useful for imaging abnormal coronary artery or peripheral PA anatomy but, even in this situation, a high-resolution CT scan may be preferable since it is noninvasive and results in less radiation exposure.

The use of cardiac MRI is limited in the preoperative evaluation of TOF patients, and is largely reserved for those

Figure 43.8. Typical ECG after TOF repair. Note the RBBB with QRSd of 180 milliseconds.

with vascular abnormalities, in particular those with major aortopulmonary collateral arteries. However, MRI has become an important component of postoperative follow-up, particularly in the older adolescent and adult with repaired TOF. The poor acoustic windows generally found in adults do not limit MRI and, furthermore, the ability to quantify RV volumes and PR is an important advantage. MRI can also be used to quantify RV (and LV) systolic function, assess differential pulmonary blood flow, quantify PR, and define the presence of restrictive RV physiology.

MRI may be particularly important in the serial follow-up of TOF patients to monitor the potentially deleterious effects of chronic PR on RV volume and function and to identify patients whose RV compensatory mechanisms are failing even before symptoms develop (140). Sufficient data have accumulated that MRI measurements are routinely applied in clinical decision making regarding interventions such as pulmonary valve replacement (PVR) (see later section). The avoidance of ionizing radiation is another important advantage of MRI, particularly if patients are to be followed regularly over decades. However, MRI is contraindicated in patients with pacemakers or defibrillators and may be limited by arrhythmia, patient claustrophobia, and the need to breath-hold effectively. In our experience, children under the age of 7 or 8 years of age usually require sedation or general anesthesia for MRI in order to prevent movement artifact during a study that may take 60 to 90 minutes.

MEDICAL TREATMENT

As will be discussed, surgical strategies for the management of patients with TOF have changed remarkably over the past few decades. In many centers, a move towards earlier corrective surgery has obviated the need for medical management in this condition. However, in some circumstances, a limited period of medical management may still be appropriate and, in the instance of an acute hypercyanotic spells, medical management can be lifesaving. Depending on the nature of their outflow tract obstruction, infants with TOF may develop symptoms related to either too little or too much pulmonary blood flow. Those who develop heart failure usually derive some benefit from pharmacotherapy (141–143), and caloric supplementation with nasogastric tube feeds allows continued weight gain (144). Infants who develop gradual, but consistent, worsening of cyanosis usually do so as a result of increasing RVOTO and will benefit little from medical therapy. In contrast, infants who develop episodic cyanosis during hypercyanotic spells usually do respond to medical therapy, both as prophylaxis and for acute treatment.

As discussed above, the pathophysiology of hypercyanotic spells should be thought of as an acute imbalance between systemic and pulmonary blood flow resulting from a vicious spiral of changes in inotropy secondary to endogenous catecholamine release, increased systemic oxygen consumption, reduced systemic vascular resistance, and reduced RV preload due to increased heart rate. The aim of therapy is to redress this imbalance and disrupt the pathophysiologic spiral by relieving pain and anxiety (to reduce heart rate and systemic oxygen consumption), increase systemic vascular resistance, and increase pulmonary blood flow. Since most hypercyanotic spells are provoked, or worsened, by crying, the infant should be picked up and comforted as soon as an episode begins, ideally while being held in a position of flexed knees and hips that kinks or compresses the femoral arteries and increases peripheral systemic vascular resistance. If no improvement is seen within a few minutes, oxygen should be administered and intravenous access obtained.

The following measures (in order of increasing intensity of intervention) can then be tried, any of which may terminate the spell (145):

- An intravenous bolus of colloid or crystalloid fluid will increase intravascular volume, maximize preload, and improve cardiac output (thereby increasing mixed venous O₂ content) and may help prevent hypotension caused by other therapeutic interventions below.
- Intravenous (or intramuscular) morphine (0.1 to 0.2 mg/kg) should be given to relieve pain and anxiety, thereby reversing endogenous catecholamine release, reducing heart rate, and lowering respiratory rate.
- Intravenous propranolol (0.015 to 0.02 mg/kg) or the shorter-acting esmolol (0.5 mg/kg given over 1 minute, thereafter continued as an infusion). Beta-receptor antagonists lower heart rate and improve diastolic ventricular filling thus increasing preload and probably also act acutely to increase systemic vascular resistance.
- Intravenous sodium bicarbonate (1 mEq/kg) may be required if there is evidence of worsening acidosis despite the measures above.
- In unremitting cases, intravenous systemic vasoconstrictors, for example, phenylephrine (boluses of 0.005 to 0.001 mg/kg), or norepinephrine (0.05 to 1.0 µg/kg/min) may be required.
- Anesthesia, intubation, and ventilation may ultimately be required to reduce the work of breathing and reduce oxygen consumption and improve mixed venous oxygen content.
- Very occasionally, severe life-threatening spells may require emergent surgical intervention or mechanical circulatory support.

Most spells are self-limiting and do not require intensive medical therapy. Many groups consider their onset as an indication for surgical correction, but interval prophylaxis with beta-receptor antagonists (oral propranolol in a dose of 0.25 to 1 mg/kg, 2 to 3 times per day) may be helpful if surgery is delayed (146).

PERCUTANEOUS PALLIATION

In an era when primary repair can be achieved in almost all infants, even during the neonatal period, with low operative mortality (147), the role of percutaneous palliation is yet to be fully determined. However, it is possible to palliate cyanotic neonates and young infants with TOF by percutaneous placement of a stent across the stenosed RVOT, which improves pulmonary blood flow and allows growth of the native pulmonary arteries (148,149). However, the procedure destroys the native pulmonary valve and so this technique should be reserved for the limited number of, usually very young, premature or small, infants in whom a transannular patch will almost certainly be necessary in any case, or in whom the pulmonary arteries are diminutive and would increase surgical mortality or morbidity (150).

THE EVOLUTION OF SURGICAL TREATMENT

Palliative Procedures

In 1930, Dr. Helen Taussig was put in charge of the newly founded Pediatric Cardiac Clinic at Johns Hopkins Hospital and, although rheumatic fever was the biggest problem

of the time, she had a keen interest in the “little cyanotic babies (referred) to the clinic as nothing could be done for them” (151). It was not long before Dr. Taussig had an idea that would change not just the outlook for her own cyanotic patients but the face of CHD forever. It was the clinical and autopsy findings of two patients that brought Dr. Taussig to the realization that infants with severe pulmonary stenosis and right heart hypoplasia died not, as was widely believed, from heart failure but because of the sudden cessation of pulmonary blood flow that occurred with closure of their arterial duct (151). After realizing the importance of a patent arterial duct to patients with limited pulmonary blood flow, Taussig recognized the potential benefit that might be possible from creation of an artificial duct. When, in 1939, Drs. Robert Gross and John Hubbard successfully ligated a persistently patent arterial duct (152), Taussig made the leap of imagination to think it “ought also to be possible to build one” (151). Subsequently (after she failed to interest Gross in the idea) she worked together with her surgical colleague in Baltimore, Dr. Alfred Blalock, and his technician, Vivian Thomas, to develop a surgically created shunt that would siphon blood from the aorta into the pulmonary arteries (151). After trialing several different techniques, the team ultimately settled on a operation performed via a thoracotomy on the opposite side to that of the patient’s aortic arch, where a direct anastomosis was formed between the subclavian branch of the innominate artery and the PA on that side (151). The first clinical shunt procedure, successfully performed in 1945, was a monumental advance and the true beginning of surgical therapy for CHD (153). Dr. Denton Cooley, who at the time was a surgical intern present in the operating room, has provided a detailed description of this first procedure and an explanation of its significance in his 2010 “Reflections of the Pioneers” essay (154). In recognition of their vital contributions, this arterial-pulmonary shunt bears both the surgeon and cardiologist’s names: the Blalock-Taussig (BT) shunt. Recognizing Dr. Thomas’ contribution, this text calls it the Blalock-Thomas-Taussig shunt (ed.). A shunt formed in this original manner (making use the native subclavian artery) is now known as a “classical” B-T-T-shunt; but in the current era, when this procedure is required, the preference is to use a prosthetic tube graft interposed between the subclavian and pulmonary arteries forming a “modified” B-T-T-shunt. Within a short period of time, other systemic-to-PA shunts were devised and used successfully: the Potts shunt (connection between the descending aorta and left PA) in 1946 (155) and the Waterston shunt (connection between the ascending aorta and right PA) in 1962 (156). Although these procedures proved useful in specific anatomical circumstances, their use never overtook that of the B-T-T shunt due to complications related to technical issues and pulmonary hypertension.

Systemic-to-PA shunts dramatically improved a patient’s clinical condition and provided reasonable mid- to long-term palliation (157–159) but, since the intracardiac defects remained, the surgery could not be considered definitive therapy. Follow-up studies of TOF patients with shunts demonstrated gradual attenuation of the initial symptomatic improvement and the late occurrence of complications such as bacterial endocarditis, cerebral abscesses, and heart failure (157–159). In 1948, Dr. Russell Brock developed a technique for direct intracardiac relief of valvar pulmonary stenosis with a knife that was passed through an incision in the RVOT and onwards, across the stenosed valve to free its leaflets (160). Dr. Brock’s technique was quickly adopted for use in TOF (162) and, since it bestowed a degree of anatomical correction, some groups favored it over shunt palliation. However, as acknowledged by all, the Brock procedure fell short of a full correction and was not without complications such as

infundibular aneurysm (163), pulmonary edema (164), and recurrent RVOTO (165).

“Complete” Surgical Repair

In 1954, Dr. C. Walton Lillehei and his colleagues repaired a VSD in an 11-year-old boy using the boy’s father’s circulation to take over the pumping and oxygenating capacity of the patient’s heart and lungs (166). “Cross-circulation” opened the doors to corrective surgery for complex CHD and, later that same year, 10-year-old Michael Eugene Shaw became the first patient with TOF to undergo successful surgical repair (167). Mr. Shaw survived to adulthood and had a successful career as a professional musician (168). Nevertheless, cross-circulation carried considerable risk to both the donor and the patient and work continued on the development of a completely artificial means of supporting the circulation during surgery; a task that had occupied John H. Gibbon and others since the 1930s (169). In 1955, Dr. John Kirklin (170) of the Mayo Clinic reported the use of a modified Gibbon heart-bypass machine in the repair of complex CHDs, including TOF. Initial mortality was high, but as early as 1959, Dr. Kirklin (171) managed to achieve postoperative survival rates as high as 83% in young children and adults with TOF. By 1964, this figure had reached 93% (172) and results from the Cleveland Clinic depicted a similar rate of progress (173). Dr. Kirklin (171,173) published a series of detailed papers explaining the developments that had contributed to these improved outcomes. He particularly commented on the need for “vigorous pursuit” of normalized postoperative blood gases and volume status, reduced use of outflow tract patches, myocardial protection strategies, and close attention to hemostasis (171,172).

During this first epoch of cardiac surgery, TOF repair was performed via either a longitudinal or transverse incision in the RV. Through this, the hypertrophied subpulmonary musculature was resected and any valvar pulmonary stenosis was relieved. Patients with an insufficiently sized pulmonary annulus were managed by extending the ventriculotomy across the valve into the main PA, so that a pericardial patch could be used to augment the outflow tract and, where necessary, the pulmonary arteries. These “transannular” patches provided complete relief of outflow tract obstruction but at the cost of destroying competency of the pulmonary valve leaflets. The VSD was closed via the ventriculotomy after reconstruction of the outflow tract. During the 1960s, most centers reserved this type of full repair for TOF patients over 4 to 6 years of age. Since attempts at full repair in infants had accrued a high mortality (174,175), cardiologists and surgeons favored a staged approach, with initial palliation by B-T-T-shunt, for those who developed severe and early cyanosis (174,176). The first successful repair of TOF in a patient <1 year-of-age was achieved by a group from Guy’s Hospital, London in 1962 (177). However, the techniques used by this group varied little from those used in previous unsuccessful attempts and throughout the 1960s; infant survivors of TOF repair remained a rare curiosity.

In the late 1960s, groups from Japan reported remarkable results from their attempts to correct CHD during the first year of life; with only 6 deaths in 78 infants, 9 of whom had undergone TOF repair (178,179). The key change was the use of deep hypothermic circulatory arrest, a technique developed by the Canadian surgeon, Dr. Bigelow (180), in the 1950s, reintroduced in Japan (178) and then popularized for use in infants and neonates with CHD by Dr. Barratt-Boyes (181) in New Zealand. However, it should be mentioned that, at the same time, Rees and Starr (182) also achieved excellent results from infant repair of TOF employing only modest hypothermia. By 1972, Dr. Barratt-Boyes’ group (183) had completely corrected the cardiac defects of 12 infants with TOF

and, of those, 11 survived to hospital discharge. In the light of his results, Dr. Barratt-Boyes (181,184) questioned whether symptomatic infants with TOF continued to be best served by a staged repair and suggested that complete primary repair might be a better option. Comparison of mortality rates before and after the introduction of complete repair during infancy lent strength to his argument (185). In New Zealand, during the era of staged palliation, survival to hospital discharge after complete repair of TOF was <50% if an infant required a shunt under the age of 4 months, and 85% if palliation was required between 4 months and 2 years (185). After changing to a strategy of complete primary repair rather than palliative shunting, mortality in the first 25 children aged under 2 years at the time of repair was only 4% (185). Impressed, Dr. Kirklin and the team at University of Alabama Medical Center completely changed their view about the timing of intracardiac TOF repair and, in 1971, all but abandoned the staged approach (186). Other centers followed suit, including the team at Boston Children's Hospital who, up until 1972, had firmly believed palliative shunts to be the preferred option for symptomatic infants but later, after Dr. Castañeda's arrival, became staunch proponents of neonatal primary repair for all infants with TOF (not just those who become symptomatic) (187–189). When follow-up studies suggested that early repair might carry hemodynamic and anatomical advantages, Dr. Castañeda and others at Boston Children's Hospital came to believe that early primary repair for all patients would not only avoid risks associated with a shunt procedure but might also reduce RV hypertrophy and promote pulmonary blood vessel growth (190,191).

Today, most centers perform elective repair of TOF in asymptomatic infants between 3 and 12 months of age (with a trend towards the lower end of the range in many large centers). For patients who become symptomatic earlier than this practice continues to vary. Some groups are staunch advocates of complete primary repair in all patients, regardless of the age at which symptoms develop, believing that the benefits of avoiding a shunt include promotion of PA growth, elimination of chronic hypoxemia, and reduced need for extensive RV muscle resection (147,192,193). Others remain concerned about the neurologic effects of neonatal cardiopulmonary bypass and hypothermic circulatory arrest and the possible increased incidence of transannular patching when operating on a very small and young baby and continue to prefer the staged (surgical or catheter-based) approach for very young symptomatic infants, with later full repair.

Coincidental to the move towards earlier complete repair, but occurring over a similar time course, surgeons also changed their operating techniques. During the earliest era of TOF repair, it was noted that residual VSDs and pulmonary stenosis were predictors of postsurgical mortality and the main causes of reoperation. Accordingly, surgeons considered the complete elimination of RVOT obstruction one of the primary aims of repair (91,171,194) and they liberally applied transannular patches to achieve this end (171). In 1963, Hudspeth et al. (195) were the first to suggest that a transatrial approach (with an atriotomy and exposure of the VSD and subpulmonary infundibulum after detachment of the septal leaflet of the tricuspid valve) might permit total correction of TOF without risk of coronary artery division, need for ventriculotomy, or external enlargement of the RVOT. Initially, Hudspeth's technique was little adopted but the method was reintroduced by Edmunds (196) in 1976 and was popularized during the 1980s with growing understanding of the long-term effects of ventriculotomy and destruction of the pulmonary valve. By the early 1990s, most centers preferentially performed TOF repair via a transatrial and transpulmonary approach, with transannular patching avoided whenever possible (95,186,197,198).

Surgical Outcomes

Since the development of the B-T-T shunt, outcomes for infants with TOF who are born in countries that can provide neonatal and infant congenital cardiac surgery and postoperative intensive care have been revolutionized. Parents of a child born with TOF can now be reassured that their baby's cardiac defect will be repaired in the first 6 months of life and that there is a >96% chance of survival to hospital discharge (132,134,199–201). Furthermore, of the surviving infants, >90% are expected to be alive 30 years after repair (202). During childhood, approximately 5% of patients require reoperation and a further 6% require catheter intervention (134). Late follow-up studies suggest a 0.8% risk per year of requiring PVR, with the highest incidence of this reintervention in patients with TOF and pulmonary atresia or TOF with absent pulmonary valve (203). This impressive subversion of natural history means that there is a large, and growing, cohort of adult TOF survivors, and for these patients (many with families of their own) and their care providers, focus has switched to late outcomes.

It is important to note that although TOF repair is now associated with little short- or medium-term mortality, long-term survival is not equal to that of the general population (197). For the 30-year-old with repaired TOF, there is a 0.5% annual risk of death (203), while according to the United States Social Security Ministry's 2006 actuarial periodic life tables (www.ssa.gov), the baseline annual probability of death for a 30-year-old male is 0.15% and for a female is 0.06%. Therefore, a 30-year-old man with TOF faces a yearly risk of death threefold higher than baseline, while a woman's risk is approximately eightfold higher. Furthermore, this increased risk of mortality increases with age (204). The most recent data suggest that the annual mortality risk for patients with TOF increases by 0.1% per decade (203). The reason that patients with TOF experience increasing adverse outcomes with age is the presence of a slowly evolving postoperative pathophysiology, which although it remains incompletely understood, has certainly become better recognized.

POSTOPERATIVE PATHOPHYSIOLOGY

While it dramatically alters a patient's life expectancy, surgical repair of TOF is not a cure and the hearts of patients with repaired TOF remain anatomically, physiologically, and electrically abnormal. Potential anatomical problems include incomplete relief of RVOTO, residual VSDs, tricuspid regurgitation, and RVOT aneurysms. Pulmonary insufficiency is probably the most important physiologic disturbance and electric problems may stem either from the RBBB or patchy ventricular fibrosis. Such abnormalities are usually well tolerated during childhood and early adult life, but extended follow-up of patients with repaired TOF has revealed the presence of a slowly progressive postoperative pathophysiology that has a pervasive influence on late outcome, with effects seen decades after repair. Adults with repaired TOF demonstrate a high frequency of exercise impairment and a small, but increasing, risk of arrhythmia, biventricular dysfunction, and premature cardiac death; outcomes that can all be related to the evolving postoperative pathophysiology (130,134,198,200–204).

Pulmonary Regurgitation and the Fate of Right Ventricle

Although many factors impact late outcomes after TOF repair, chronic PR is widely recognized as a key pathophysiological

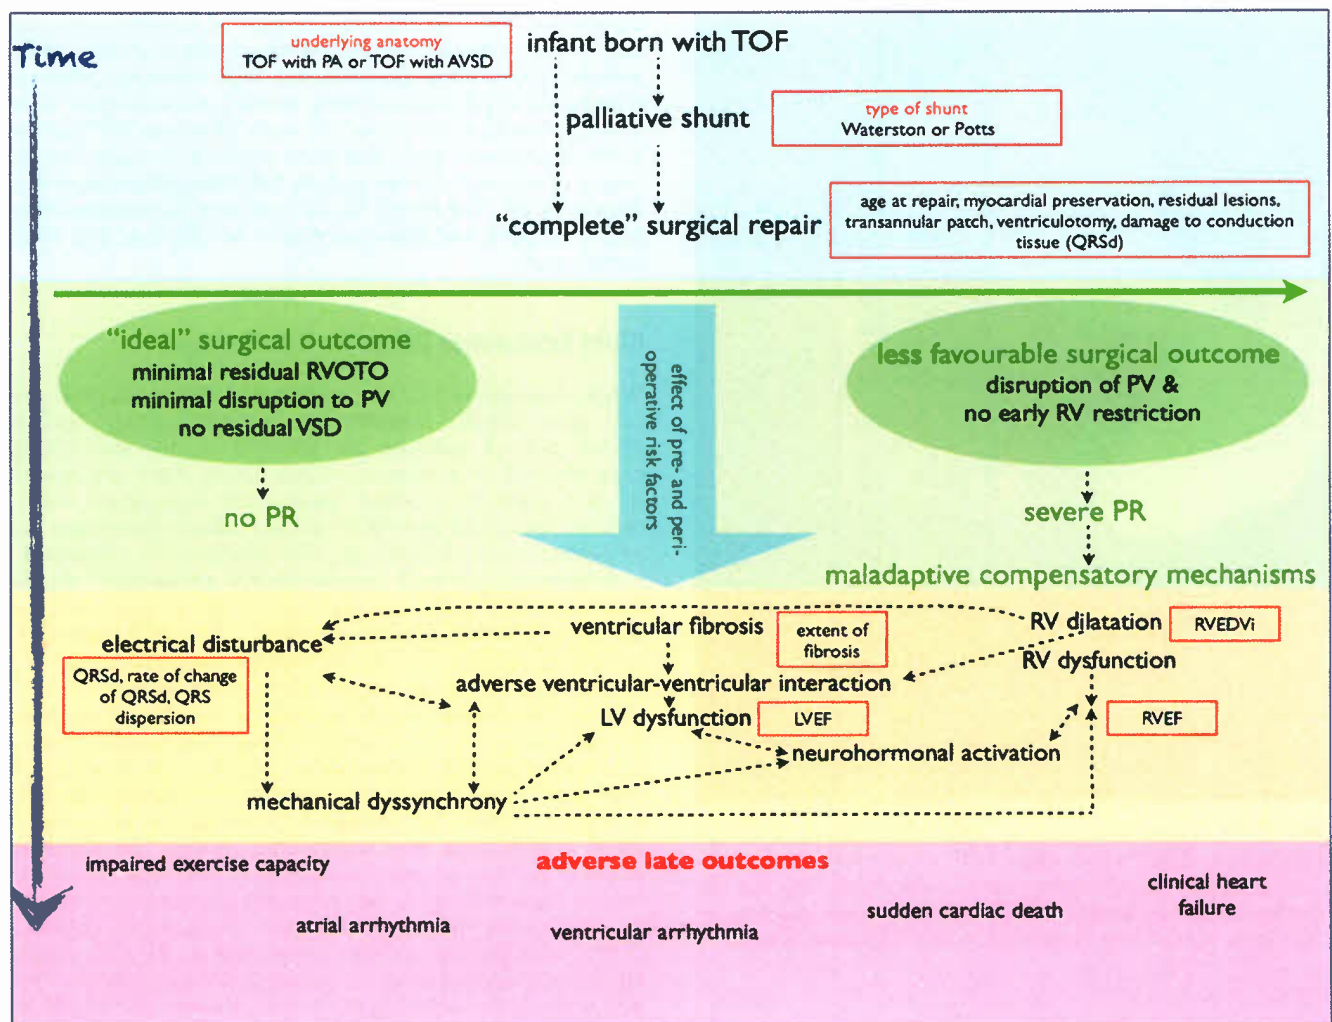

Figure 43.9. Pathophysiology after TOF repair—red boxes indicate known risk factors for late outcomes.

driver (Fig. 43.9) (210–215). A common sequel of TOF repair, PR is especially likely, and most severe in patients with a transannular patch. Unfortunately, PR tends to increase with time (216,217) and places a volume load on the RV that is exacerbated by any distal PA stenosis (217,218). It has come to be understood that the RV responds to chronic volume loading with an adaptive remodeling, which while initially compensatory, ultimately proves detrimental. In the face of chronic PR, compensatory RV dilation and hypertrophy maintain forward flow and wall stress (Fig. 43.10). An association between pulmonary insufficiency and RV end-diastolic volumes in patients with TOF was first recognized in the 1980s (219,220) and the strong positive relationship became easier to demonstrate with the advent of MRI (221). RV dilation is not initially associated with a reduction in RV ejection fraction (219,221) and stroke volume is maintained, so that patients experience a long preclinical compensated phase during which they rarely report symptoms (Fig. 43.9). Nevertheless, formal testing during these decades often reveals impaired exercise capacity (222) and neurohormonal activation that correlates with RV volumes (223–225). Ultimately, RV compensatory adaptations become inadequate and TOF patients with severe PR begin to develop RV contractile dysfunction (210,211,215). Pathophysiologic progression can be exacerbated by coexisting abnormalities. For example, tricuspid regurgitation (present in around 30% of patients [226]) produces a cycle of worsening RV

dilation, leading to worsening tricuspid regurgitation, leading to worsening RV dilation etc. (227). For a period of time, RV dysfunction remains reversible with intervention to abolish PR (140,227–230) but, eventually, the damage progresses and permanent myocardial injury ensues. This manifests as an inability of the RV to regain normal dimensions, even after PVR (231) and as overt RV failure with increased risk of ventricular arrhythmia and sudden cardiac death (203,204,232).

Ventricular Fibrosis

Many studies have demonstrated ventricular fibrosis in patients with repaired TOF and several have linked the extent of fibrosis to late complications such as arrhythmia, systolic dysfunction, exercise intolerance, and neurohormonal activation (233–236). It seems that almost all adults with repaired TOF exhibit markers of RVOT fibrosis (whether or not a transannular patch has been placed) and this correlates with both regional and global abnormalities of RV function (233,235,236). Over half of the patients also have patchy LV fibrosis; sometimes correlating with the site of an apical vent from the time of cardiopulmonary bypass (233). Those repaired at older ages have the most fibrosis, suggesting that pre- and perioperative factors are the most important insults (233). The extent to which ongoing pathophysiologic processes (i.e., severe PI)

Figure 43.10. Three dimensional MRI rendered image of left and right ventricle 8 years after TOF repair. RV shaded yellow, LV shaded red. Note the size disproportion between the ventricles caused by severe RV dilatation. (Image courtesy of Dr. Shi-Joon Yoo of The Hospital for Sick Children, Toronto.)

cause the further development of postoperative fibrosis is not yet known.

Mechanoelectrical Interactions

A leap forward in understanding the late outcomes after TOF repair occurred with the realization that, along with direct mechanical effects, chronic PR also causes electrical deterioration of the heart and that the two are pathophysiologically linked (136,237). In 1995, Gatzoulis et al. (237) correlated RV dilation with QRS prolongation and identified QRSd as an important predictor of adverse outcomes late after TOF repair. The group studied 41 randomly selected TOF patients 15 or more years after repair, then tested their findings in a second group of 178 patients (237). They found a QRSd of ≥ 180 milliseconds to be a sensitive and specific predictor of later symptomatic ventricular tachycardia and/or sudden cardiac death (237). Patients with a QRSd of ≥ 180 milliseconds also had increased cardiothoracic ratio (a surrogate for RV size) and increased longitudinal RV dimensions, whereas those without PR consistently demonstrated a QRSd of < 180 milliseconds (237). Several years later, in collaboration with others, the same group conducted a multicenter investigation of nearly 800 TOF patients that confirmed the importance of adverse mechanoelectrical interactions (136). Increased cardiothoracic ratio, QRSd prolongation, and the requirement for TAP were each associated with adverse outcomes and both a QRSd ≥ 180 milliseconds and the rate of QRSd progression (> 5 milliseconds per year over a 10 year period) were predictive of sudden cardiac death (136). These studies changed not just the way the postoperative pathophysiology of TOF is

understood but also the management of patients, since most centers now consider absolute or rapid rate of change of QRS prolongation in their algorithm for PVR. However, when considering the implications of these studies, it is important to note that it followed patients repaired in an earlier era (91% of those in the multicenter study had been repaired via right ventriculotomy [136]) and did not include MRI quantification of either RV size or PR. The thresholds for intervention in more contemporary cohorts will almost certainly be different and deserve further study.

Right Ventricular Diastolic Dysfunction

While disruption of the pulmonary valve during surgical repair usually initiates the pathophysiology described above, not all patients are affected in this way. Despite near absence of pulmonary valve tissue, there is a minority of TOF patients in whom pulmonary regurgitant volumes remain low and whose RVs do not dilate during the years of postoperative follow-up. The difference is explained by a phenomenon termed “restrictive RV physiology” that was first identified in infants during the immediate postoperative period but has also been seen in adults and children late after TOF repair (215). In the mid-1990s, Cullen et al. (238) identified a group of infants with postoperative RV diastolic dysfunction set apart by their more difficult postoperative course and a set of specific echocardiographic findings. When studied with pulsed-wave Doppler echocardiography, these patients demonstrated antegrade diastolic blood flow in the PA (238). The timing of PA antegrade flow matched atrial systole and was augmented during the expiratory phase of positive pressure ventilation (238). For reasons that remain incompletely understood but are suspected to relate to inadequate intraoperative RV myocardial protection (239), such patients exhibit restriction to RV late diastolic filling as a consequence of reduced RV compliance (240). When the atria contract, the pressure wave and blood flow are transmitted directly to the PA, because the resistance to pulmonary flow is less than the resistance to RV stretch. In the mid-term (2 years postrepair) postoperative restriction predicts later restrictive physiology (241) but long-term prospective studies with serial follow-up are lacking.

A stiff RV resists not only filling through the tricuspid valve but also filling from PR theoretically limiting RV volume loading and its subsequent deleterious effects. To this end, while restrictive RV physiology is disadvantageous in the early postoperative period, because it causes low cardiac output, it may be protective in the longer term. Gatzoulis et al. (237) demonstrated that adult TOF patients with restrictive physiology have a smaller cardiothoracic ratio, an improved exercise capacity, and a shorter QRSd than those without RV restriction. Interestingly, groups that used MRI to determine the presence of restrictive physiology have found results somewhat at odds with those of Gatzoulis et al. (240,242). For example, Helbing et al. (242) found their patients with restrictive physiology to have reduced, rather than improved, exercise tolerance and, although Apitz et al. (240) were the first to demonstrate that TOF patients have increased RV stiffness, they found no difference in MRI measurements of RV volume between the “restrictive” and “nonrestrictive” groups. Their results might be explained by the fact that children were studied rather than adults (perhaps there had been insufficient time to detect the RV effects of chronic volume loading) but the discrepancies between Gatzoulis’ and Helbing’s results are more difficult to explain. The answer may lie in the differences in the methodologies used to determine RV restriction. Indeed, this may go some way towards explaining the wide range of prevalence for restriction reported by the various studies, since

the reported prevalence of restrictive physiology in patients with TOF varies from 28% to 67% (238,242–245).

The Role of Pulmonary Valve Replacement

PVR is one of the commonest procedures performed in adults with CHD (246) with a risk of operative mortality generally quoted at around 1% (140). Today, given suitable anatomy, PVR can even be achieved without recourse to open heart surgery using percutaneous techniques (247,248), although this technique is currently largely reserved for those with an RV-PA conduit or previous stenting of the RVOT. Given the long-term adverse influences of chronic PR, insertion of a competent pulmonary valve is clearly an attractive option. However, no replacement valve has an infinite lifespan and PVR usually commits patients to at least one additional operation or procedure during their lifetime. In addition, PVR remains a relatively expensive and invasive procedure and, while the risk of procedural complications is low, it is not zero. So, before recommending PVR to an individual, the physician must first consider whether the benefits outweigh the risks and, if so, determine optimal timing for the procedure. These have become central questions for those caring for patients with repaired TOF. Unfortunately as yet, the literature contains no definite answers.

Although two studies have made attempts at retrospective case–control “matching” (249,250), to date, there have been no randomized controlled trials examining the impact of PVR. It is fairly clear that PVR improves exercise tolerance and symptoms in patients with PR after TOF repair (230,231,249,251–253) but there are no definitive data as to whether PVR also favorably modifies late clinical outcomes. For this reason, while most centers recommend PVR for TOF patients complaining of symptoms related to their hemodynamic load, criteria vary widely when considering PVR in asymptomatic patients. The key considerations are usually RV size, QRSd, formally documented exercise capacity, and biventricular function.

There is evidence that RV dilation reaches a threshold, beyond which reverse remodeling is unlikely even after PVR (228,254,255). Consequently, most centers consider PVR in patients with progressive RV dilation or RV end-diastolic volumes that approach 160 to 180 mL/m², with the exact number dependent on local policies. However, these thresholds are somewhat arbitrary since MRI methods for measuring RV volumes are not standardized, studies from which the cutoffs are drawn include fewer than 100 patients, and no study has shown that clinical outcomes are worse in patients whose RV volumes fail to normalize after PVR.

Given the evidence that prolonged QRSd increases the risk of life-threatening arrhythmia and sudden cardiac death late after TOF repair, most centers consider a QRSd of ≥ 180 milliseconds, or one that is rapidly increasing, an indication for PVR. Studies that have specifically considered the electrical implications of PVR do suggest it reduces QRSd in association with a reduction in RV size and that PVR reduces the incidence of arrhythmia in individual patients (255–257). However, most studies included some patients who underwent electrophysiologic ablation in conjunction with PVR and it is difficult to tease out which procedure had the most effect (257,258). Certainly patients who undergo ablation as well as PVR seem most likely to remain arrhythmia-free, with ablation particularly effective against SVT (257,258).

Ventricular–Ventricular Interactions and the Fate of the Left Ventricle

Of the thousands of papers published regarding TOF, hundreds discuss the RV, its outflow tract, and the pulmonary arteries.

In contrast, fewer than 40 papers consider the effects TOF might have on the LV. In the minds of many, TOF remains a disease entirely of the right heart. This is a perception that needs to change, since it has become increasingly evident that the LV is intimately involved in the postoperative pathophysiology of TOF and plays an important role in long-term clinical outcomes.

Apart from a few conflicting studies during the earliest era of TOF repair (259–261) and a handful from the 1980s and 1990s (262–265), the fate of the LV after TOF repair received little attention until 2002, when Ghai et al. (206) discovered LV dysfunction late after TOF repair to be a risk factor for sudden cardiac death (201). Several years later, the same group used MRI to conduct a more quantitative study in an attempt to uncover the mechanisms of LV dysfunction (266). The investigators found that in a group of 75 adult patients with TOF, prolonged QRSd was associated with increased size and decreased ejection fraction of both ventricles (266). The QRSd was also associated with heterogeneous LV contraction, presumably induced by RBBB, and the authors proposed that, in combination with RV dysfunction, LV dyssynchrony and adverse LV mechanics might explain the link between QRSd and adverse clinical outcomes (266). Geva et al. (267) also highlighted the importance of the LV in patients with repaired TOF when they found LV ejection fraction (LVEF) to be a primary determinant of late clinical status. The group’s results seem to suggest that although RV mechanics relate to functional status late after repair, moderate or severe LV impairment might yet be the strongest determinant of clinical symptoms (267).

Since the right and left ventricles share common myocardial strands (268,269), an interventricular septum and pericardium, it is to be expected that processes affecting the RV may also impact the LV, a concept known as ventricular–ventricular interaction (see Chapter 22). As well as anatomical considerations, there are physiologic factors linking the ventricles. Blood moved through the lungs by the RV immediately becomes LV preload, so that problems such as pulmonary stenosis or regurgitation threaten LV preload and cardiac output. Furthermore, when the RV changes shape and/or size, it alters the shape and size of the LV. Even in health, the filling of one ventricle influences the compliance and filling of the other (diastolic ventricular–ventricular interaction). For instance, an elevation of RV end-diastolic pressure increases LV end-diastolic pressure (270) and shifts the septum towards the left. In 1983, Kingma et al. (271) demonstrated in an animal model that it is the transseptal pressure gradient that determines the position of the ventricular septum at end-diastole. Thus, if RV end-diastolic pressure is higher than LV end-diastolic pressure (as occurs with either RV volume or pressure overload), the septum flattens at end-diastole and moves towards the LV cavity that affects LV filling. In the subsequent systole, initial movement of the septum is back towards the neutral position (to the right) and this creates paradoxical septal motion. Ventricular–ventricular interactions (both systolic and diastolic) are certainly relevant to the postoperative pathophysiology of patients with repaired TOF as evidenced by several studies that demonstrate a strong positive correlation between RVEF and LVEF (266,267,272). However, the clinical meaning and the mechanisms underlying this relationship remain uncertain. Does it imply that intrinsic contractile function of the myocardium in each ventricle is interdependent? Or rather, given the known load dependency of ejection fraction, does it tell us more about the effects of a dilated RV and paradoxical septum on LV filling? In patients with impaired LVEF and severe PR, demonstrable improvements in LVEF are seen after PVR supporting the concept that adverse ventricular–ventricular interactions may be reversible (273).

Quite separate from the potential for adverse ventricular–ventricular interactions are the unique anatomical

and perioperative factors that might directly affect the left ventricular myocardium of individual patients. For instance, it is conceivable that abnormal coronary artery anatomy, prolonged periods of deep cyanosis (hypercyanotic spells), and LV volume overloading as a result of palliative shunting might cause LV hypoxic or ischemic damage. Davlouros et al. (267) found three independent predictors of LVEF, measured by MRI at a mean of 24 years after complete TOF repair, including RVEF, duration of palliation prerepair, and aortic regurgitation.

If we are to understand the true mechanisms by which this primarily “right-sided” CHD is able to affect the LV and thereby increase the risk of sudden death and symptomatic heart failure, investigators must consider both the significance of perioperative and patient-specific factors as well as the role of adverse ventricular–ventricular and diastolic–systolic interactions.

The Aortic Root

In fetuses with TOF, the diameter of the ascending aorta is usually normal for gestational age at the time of diagnosis but serial measurements reveal accelerated growth during fetal life, particularly in those with most severe RVOTO (87). By the time of birth, the ascending aorta of infants with TOF is not just increased relative to the PA, its absolute diameter is enlarged (87). It is presumed that this enlargement occurs as a result of the increased volume load on the developing aorta, which must carry more of the blood ejected from both ventricles than in fetuses with a normal unobstructed RVOT. However, there are also aortic root histologic (274) and elastic (275) abnormalities in these patients, and it seems likely that these, too, play a role. While rarely a problem in childhood, dilation of the aortic root can cause clinical problems in adults with TOF. The most frequent issue is aortic insufficiency, with a reported prevalence of more than mild aortic regurgitation in 6.6% of patients 15 years postrepair (271) and the occasional requirement for aortic valve replacement (272). There are case reports of aortic dissection in patients with TOF and severe aortic dilation (278,279), but this is an extremely rare complication. In the two published reports of dissection, one patient's aortic root measured 6.5 cm and his ascending aorta 7.1 cm in diameter (278) and the other's ascending aorta measured 9.3 × 8.3 cm (279). In 2010, François et al. (280) reported serial aortic root measurements adjusted for body surface area in 88 children who underwent TOF repair at a median age of 7 months. All aortic root measurements were enlarged at the time of repair, but within 7 years, the annulus and sinotubular Z-scores had returned to normal and the aortic sinus measurements showed significant regression (280). These retrospective data are interesting because they suggest that early repair might prevent aortic dilation; however, given the known abnormalities of aortic tissue in patients with TOF, further follow-up will be required before definite conclusions can be drawn.

OTHER ISSUES FOR ADULT LIFE

Monitoring for Late Complications

Since the 1960s, after undergoing surgical intervention, most infants born with TOF have survived into adulthood. As a result, there are large numbers of adults living with this condition and, since several programs have reported their long-term outcome data, much is known about what those born with this CHD might expect to face as they move through adult life. The European, American, and Canadian guidelines for the

care of adults with CHD all recommend lifelong follow-up of patients with TOF in a specialist center by physicians with expertise in adult CHD. These guidelines suggest that for the majority of patients, the frequency of review should be annual, but those with an excellent surgical outcome or who remain stable might be followed less frequently.

The purpose of routine follow-up is to anticipate and monitor potential complications and, when necessary, to intervene before these become clinically important. Regular visits also provide an opportunity for patient education and advice on maintaining a healthy lifestyle. In addition to an assessment of a patient's general wellbeing, routine follow-up visits should specifically evaluate the presence and effects of: PR, residual RVOTO including branch pulmonary arteries, residual VSD, RV dysfunction, aortic root dilation, aortic insufficiency, and LV dysfunction. An ECG should be recorded at each visit, so that the QRSd can be recorded and any progression can be monitored over time. Routine Holter monitoring has not proven useful for predicting clinically important arrhythmias but patients should be asked about symptoms of palpitations and syncope. Echocardiography should be performed at each visit and regular cardiopulmonary exercise testing is useful to formally document changes in exercise capacity. Cardiac MRI should be performed at regular intervals, particularly in patients with severe PR to quantify RV volumes and biventricular function. Cardiac tomography (CT) is an alternative for patients with pacemakers/defibrillators. The frequency of cardiopulmonary studies and MRI/CT is determined on an individual patient basis. In patients for whom further interventions are planned, cardiac catheterization is sometimes necessary to assess hemodynamics and anatomy and, in middle-aged patients, to exclude atherosclerotic coronary artery disease.

The Timing of Pulmonary Valve Replacement

Patients with moderate to severe PR clearly need monitoring for possible PVR. However, as discussed earlier, at present there is no consensus as to the indications and optimal timing of this procedure. Decisions surrounding PVR remain one of the biggest challenges in this population, with each adult CHD center having their own policies. Most centers would intervene in patients with symptoms attributable to PR, and in asymptomatic patients, RV size, exercise capacity, and QRSd are important factors in decision making.

Monitoring after Pulmonary Valve Replacement

Since no artificial valve has an indefinite lifespan, after PVR patients require regular (every 1 to 2 years) echocardiograms to monitor the function of their new bioprosthetic valve or RV-to-PA conduit. If they become significantly stenosed or regurgitant, surgically placed valves can often be re-replaced nonsurgically with the previous percutaneously implanted valve providing support for the new valve. A metallic valve is rarely chosen for PVR but, if it is, patients will require anticoagulation and appropriate monitoring.

Endocarditis

Endocarditis is rare after TOF repair but increases in frequency after PVR. At clinic visits, patients should be reminded of the symptoms of endocarditis and of the importance of maintaining excellent oral hygiene. Current guidelines should be consulted but, in general, antibiotic prophylaxis is only recommended for those patients with conduits and prosthetic valves.

Contraception and Pregnancy after Tetralogy of Fallot Repair

Issues surrounding contraception and pregnancy should be introduced early to female adolescents with TOF and discussed regularly. Issues regarding genetics, recurrence risk, and fetal screening should also be discussed with male TOF patients. The majority of women with repaired TOF will be able to choose from the full range of available contraceptive options. Caution with combined hormonal preparations is required in women with significant ventricular dysfunction or atrial arrhythmias because of the associated thromboembolic risks of estrogen (281,282). In general, pregnancy is well tolerated in women with repaired TOF. For any individual patient, the risks of pregnancy depend on the severity of any residual lesions, the degree of any ventricular dysfunction, and the likelihood of developing an arrhythmia. The long-term effects of pregnancy on women with TOF (if any) are, as yet, unknown. Ideally, all women with CHD who are considering pregnancy should be directed to specialists with expertise and experience in managing such patients, so as to discuss their individual risks and optimize their care through pregnancy and delivery. For further information, see this book's chapter on pregnancy in CHD and other specialist resources, for example, www.heartdiseaseandpregnancy.com.

Allison K. Cabalka ■ William D. Edwards ■ Joseph A. Dearani

Persistent truncus arteriosus is an uncommon congenital cardiovascular malformation. There is not a striking gender difference in frequency, although most series contained more male than female subjects. Truncus arteriosus usually occurs as an isolated cardiovascular malformation, although on occasion it has been reported in association with anomalies of other systems, particularly the DiGeorge or velocardiofacial syndrome (microdeletion chromosome 22q11.2) (1–4). Maternal diabetes has been implicated as a risk factor for truncus arteriosus. The anomaly has occurred in dizygotic twins (5) and siblings, and there is an increased incidence of cardiac malformations in relatives of children with this lesion (6–8). Because corrective operation for this malformation was first performed more than 30 years ago (9), ever-increasing numbers of postoperative patients now are reaching adolescence and adulthood. Patients who have had truncus arteriosus corrected need continued follow-up care throughout life. During the last 25 years, surgical correction of truncus arteriosus during infancy has become routine (10,11).

EMBRYOLOGY

The embryonic truncus arteriosus lies between the conus cordis proximally and the aortic sac and aortic arch system distally. Partitioning of the truncus arteriosus, which is intimately associated with conal and aortopulmonary septation, was reviewed by Van Mierop et al. (12) and more recently by Bartelings and Gittenberger-de Groot (13). Truncus swellings, similar in appearance to endocardial cushions, divide the truncal lumen into two channels: the proximal ascending aorta and the pulmonary trunk. As the proximal portion of this truncal septum fuses with the developing conal septum (derived from conal swellings), the right ventricular origin of the pulmonary trunk and the left ventricular origin of the aorta are established. Valve swellings develop from truncal tissue at this line of fusion, and the excavation of these swellings leads to formation of the aortic and pulmonary valves in their respective sinuses. Along the aortic sac, the paired sixth aortic arches (primitive pulmonary arteries) migrate leftward, and the paired fourth aortic arches shift rightward. Invagination of the aortic sac roof thereby forms an aortopulmonary septum that eventually fuses with the distal extent of the truncal septum. Accordingly, the right and left pulmonary arteries originate from the pulmonary trunk, and the aortic arch emanates from the ascending aorta. The spiral course of the trunco-aortic partition produces the normal intertwining of the great arteries.

When conotruncal or trunco-aortic septation does not proceed normally, various congenital ventriculoarterial anomalies may result (12). One of these anomalies is truncus arteriosus, in which a single arterial trunk exits from the heart. Also, either deficiency or absence of the conal (infundibular) septum produces a large ventricular septal defect. Because the conal septum also contributes to the development of the anterior tricuspid leaflet and the medial tricuspid papillary muscle, these structures may be malformed. The single truncal valve may be deformed and functionally insufficient or, less commonly, stenotic (14). If vestiges of distal trunco-aortic septation develop, the pulmonary arteries may arise together from a short pulmonary trunk; otherwise, they arise separately from the truncal root.

PATHOLOGY

Truncus arteriosus is characterized by a single arterial vessel that arises from the base of the heart and gives origin to the coronary, pulmonary, and systemic arteries (Fig. 44.1). Origin of the pulmonary arteries from this single artery serves to differentiate truncus arteriosus from pulmonary valve atresia, a condition in which a single arterial vessel also receives the entire output of both ventricles but in which the pulmonary arteries do not arise directly from the ascending portion of this single great artery. Collett and Edwards (15) recognized four types of truncus arteriosus on the basis of the anatomic origin of the pulmonary arteries. In type I, a short pulmonary trunk originating from the truncus arteriosus gives rise to both pulmonary arteries. When both pulmonary arteries separate from the truncus arteriosus, with no vestige of a main pulmonary artery (MPA), they may arise close to one another (type II) or at some distance from one another (type III). The type IV truncus arteriosus is now considered to represent a form of pulmonary atresia with ventricular septal defect and is not discussed further in this chapter.

Van Praagh and Van Praagh (16) have proposed an expanded classification system that also includes two commonly associated abnormalities of the great arteries. Their type A1 corresponds to type I of Collett and Edwards, and type A2 encompasses types II and III (Fig. 44.2). Type A3 includes cases with absence of truncal origin of one pulmonary artery, with blood supply to that lung from the ductus arteriosus or from a collateral artery. Last, type A4 is associated with underdevelopment of the aortic arch, including tubular hypoplasia, discrete coarctation, or complete interruption.

Figure 44.1. Pathology of truncus arteriosus: Right ventricular view showing truncal origin of aorta, right (R) and left (L) pulmonary arteries (type II), and coronary arteries. Ventricular septal defect (D) is cradled between superior (SL) and inferior (IL) limbs of septal band (SB). Fusion of inferior limb with parietal band (PB) separates tricuspid valve from bicuspid truncal valve and mitral valve. Infundibular septum and medial tricuspid papillary muscle are absent. Aortic arch is right-sided. LBr, left bronchus; LPA, left pulmonary artery; Tr, trachea.

The ventricular septal defect in truncus arteriosus is generally large and results from either absence or pronounced deficiency of the infundibular septum. The defect is cradled between the two limbs of the septal band and is roofed by the truncal valve cusps (Fig. 44.1). In most instances, fusion of the inferior limb and the parietal band causes muscular discontinuity between the tricuspid valve and the truncal valve (15). Accordingly, the membranous septum is intact, and the defect is of the infundibular type. When such fusion fails to occur, tricuspid–truncal valvular continuity is present, and the defect (which now involves the membranous septum) is of combined membranous and infundibular types. Rarely, the ventricular septal defect in truncus arteriosus may be small and restrictive or even absent (17).

Among 400 cases of truncus arteriosus from four publications reviewed by Fuglestad et al. (14), the truncal valve was tricuspid in 277 (69%), quadricuspid in 86 (22%), bicuspid in 35 (9%), pentacuspid in 1 (0.3%), and unicommissural in 1 (0.3%). The semilunar valve is in fibrous continuity with the mitral valve in all patients but is continuous with the tricuspid valve in only a minority. By overriding the ventricular septum, the truncus arteriosus has a biventricular origin

in 68% to 83% of patients (15,18). In 11% to 29% of patients, the truncal valve arises entirely from the right ventricle, whereas in 4% to 6% of patients, it emanates entirely from the left ventricle.

The anatomic cause for truncal valve insufficiency is variable and includes thickened and nodular dysplastic cusps, prolapse of unsupported cusps or of conjoined cusps with only a shallow raphe, inequality of cusp size, minor commissural abnormalities, and annular dilation (14,19). Truncal valve stenosis, when present, usually is associated with nodular and dysplastic cusps (19). The truncal root frequently is dilated, and the truncal sinuses often are poorly developed.

A right aortic arch with mirror-image brachiocephalic branching, occurring in 21% to 36% of patients (19,20), is associated more commonly with truncus arteriosus than with any other congenital cardiac malformation except pulmonary atresia with ventricular septal defect. Rarely, a double aortic arch persists. Hypoplasia of the arch, either with or without coarctation of the aorta, occurs in 3% of patients (18). Interrupted aortic arch occurs relatively frequently (11% to 19% of patients) (19,21) and is accompanied by ductal continuity of the descending thoracic aorta. It frequently is associated with the DiGeorge syndrome.

The ductus arteriosus is absent in approximately half of patients with truncus arteriosus, but it remains patent postnatally in nearly two-thirds of patients in whom it is present. The relative sizes of the aorta and the ductus arteriosus tend to vary inversely, such that the ductus arteriosus is particularly large in patients with underdevelopment of the aortic arch (type A4 truncus).

The pulmonary arteries most commonly arise from the left posterolateral aspect of the truncus arteriosus, a small distance above the truncal valve. Type I truncus arteriosus is observed in 48% to 68% of patients, type II in 29% to 48% (18), and type III in 6% to 10% (15,18). In type II, the left pulmonary artery ostium generally is somewhat higher than that of the right pulmonary artery. Rarely, in the setting of interrupted aortic arch, this ostium may arise to the right of the right pulmonary artery ostium and cause crossing of the pulmonary arteries posterior to the truncus arteriosus (19).

Stenosis of the pulmonary artery ostia or arteries is uncommon. In rare instances, deformed truncal valvular tissue may obstruct the pulmonary ostia during ventricular systole. In general, however, unless pulmonary arterial banding is performed, the pulmonary vascular bed will be exposed to systemic arterial pressure.

In truncus arteriosus, one pulmonary artery may be absent. Of the Mayo Clinic's previously published series of patients with truncus arteriosus, 16% (11 of 70) had only a single pulmonary artery (22). In 9 of the 11 patients, the pulmonary artery was absent on the side of the aortic arch. Thus, in truncus arteriosus, the pulmonary artery most frequently is absent on the side of the aortic arch, in contrast to tetralogy of Fallot, in which the pulmonary artery more frequently is absent on the side opposite the aortic arch.

This chapter does not consider either so-called pseudotruncus arteriosus, which is actually a form of pulmonary valve atresia with ventricular septal defect, or "hemitruncus," in which one pulmonary artery arises from the ascending aorta and the other emanates from the right ventricle and clearly has a well-developed pulmonary valve at its origin. The embryologic basis for these deformities appears to be different from that for true persistent truncus arteriosus.

Knowledge of variations in coronary arterial origin and distribution, which are common in truncus arteriosus, is important to the surgeon. Because the left anterior descending coronary artery frequently is relatively small and displaced leftward, the conus branch of the right coronary artery, in a compensatory manner, is usually prominent and supplies several large branches to the right ventricular outflow tract

Figure 44.2. Classification systems for persistent truncus arteriosus. **Top:** Type I to IV. (Collett RW, Edwards JE. Persistent truncus arteriosus: a classification according to anatomic types. *Surg Clin North Am* 1949;29:1245–1270.) **Bottom:** Types A1 to A4. (Van Praagh R, Van Praagh S. The anatomy of common aorticopulmonary trunk (truncus arteriosus communis) and its embryologic implications: a study of 57 necropsy cases. *Am J Cardiol* 1965;16:406–425.) (See text for description for each type.)

(23,24). The posterior descending coronary artery arises from the left circumflex artery (left coronary dominance) in 27% of patients with truncus arteriosus (25), which is about three times the frequency of this variation in the normal population. Anomalies of coronary ostial origin, involving 37% to 49% of patients with truncus arteriosus (25), are common, regardless of the number of truncal valve cusps. In general, however, the left coronary artery tends to arise from the left posterolateral truncal surface and the right coronary artery from the right anterolateral surface (18,25).

In the setting of a single coronary ostium, frequently associated with left coronary dominance, all three major epicardial branches originate from this common site, or the right coronary artery may be absent (19). When two ostia exist, both may arise from the same truncal sinus; one may take origin from the expected site of the noncoronary sinus, or both may arise normally. High ostial origin, above the truncal sinotubular junction, occurs often, but when the origin is at or slightly above a truncal valve commissure, the involved ostium (most commonly the left) may be slit-like and functionally stenotic. Conceivably, dysplastic valvular tissue also could obstruct an otherwise normal coronary ostium. Rarely, the left coronary artery originates from the pulmonary trunk (18,26). Combinations of the aforementioned coronary anomalies frequently are observed.

The location of the conduction tissue in truncus arteriosus is also of surgical importance. The sinus node and the atrioventricular node are normal in location and structure. The atrioventricular bundle courses to the left of the central fibrous body, and the left bundle branch emanates along the left ventricular septal subendocardium, just beneath the membranous septum (27). The right bundle branch travels within the myocardium of the ventricular septal summit, attaining a subendocardial course at the level of the moderator band. In most instances in which the ventricular septal defect is truly infundibular and the membranous septum is intact, the

atrioventricular conduction tissue is somewhat distant from the rim of the defect. In patients with combined membranous-infundibular ventricular septal defect, however, the conduction tissue passes along the left aspect of the posterior-inferior rim of the defect.

The anomalies most commonly associated with truncus arteriosus are right aortic arch, interrupted aortic arch, absent ductus arteriosus, patent ductus arteriosus, unilateral absence of a pulmonary artery, coronary ostial anomalies, and an incompetent truncal valve. A secundum atrial septal defect has been noted in 9% to 20% of patients, an aberrant subclavian artery in 4% to 10%, a persistent left superior vena cava draining into the coronary sinus in 4% to 9%, and mild tricuspid stenosis in 6% (18,20). Total or partial anomalous pulmonary venous connection in association with truncus arteriosus also has been described (22,28). Rare associated anomalies that have been reported include tricuspid atresia, mitral atresia, ventricular inversion, and association with the asplenia complex. We have encountered one patient with both truncus arteriosus and complete atrioventricular septal defect. Extracardiac anomalies, present in 21% to 30% of autopsy cases of truncus arteriosus, include skeletal deformities, hydroureter, bowel malrotation, and multiple complex anomalies.

Among the secondary complications of truncus arteriosus, biventricular hypertrophy is frequent, and dilation of ventricular chambers is prominent when truncal valve insufficiency exists. If there is massive cardiac hypertrophy, chronic subendocardial myocardial ischemia may develop (even with normal epicardial coronary arteries). As a result of chronic exposure of the pulmonary vasculature to systemic arterial pressure, hypertensive pulmonary vascular disease (plexogenic pulmonary arteriopathy) may develop. The arteriolar lesions often develop more rapidly and to a more severe extent in truncus arteriosus than in isolated ventricular septal defect. With chronic truncal valve insufficiency, pulmonary venous hypertension also may develop.

As patients with surgical repair survive into adulthood, progressive dilation of their aorta (original truncal artery) often occurs but is rarely associated with complications, including dissection or rupture (29).

MANIFESTATIONS

Clinical Features

In most patients with truncus arteriosus, congenital heart disease is recognized during early infancy, often during the neonatal period. During the 1990s, intrauterine diagnosis became possible with fetal echocardiography (30). The clinical features depend largely on the volume of pulmonary blood flow and whether associated significant truncal valve insufficiency is present.

During the first weeks of life, persistence of increased pulmonary arteriolar resistance present during fetal life may cause mild cyanosis with little evidence of cardiac decompensation, unless severe truncal valve insufficiency also is present. As pulmonary resistance gradually decreases and flow through the lungs increases, the cyanosis may disappear. However, tachypnea, tachycardia, excessive sweating, poor feeding, and other signs of pulmonary overcirculation may appear. If truncal valve insufficiency is severe, the signs and symptoms of heart failure may appear shortly after birth. The additional volume load produced by this associated problem always adds to the increasing demands placed on the heart as pulmonary flow increases.

In the uncommon situation in which the infant has naturally occurring stenosis of the pulmonary arteries, cyanosis may be present at birth and may intensify with increasing age. However, such stenosis protects the child from pulmonary overcirculation that would otherwise occur with falling pulmonary resistance. Severe cyanosis, in addition to the signs of heart failure, may be present early if the child has both naturally occurring stenosis of the pulmonary artery and severe insufficiency of the truncal valve.

Physical Examination

Physical findings are related primarily to the volume of pulmonary blood flow and the presence or absence of truncal valve insufficiency. Patients with increased pulmonary blood flow have little or no cyanosis. The peripheral pulses are accentuated and may be bounding. The pulse pressure usually is increased owing to runoff into the pulmonary vascular bed during diastole and is accentuated in the setting of truncal valve insufficiency. A left precordial bulge may be noted, and a systolic thrill often is palpable along the left sternal border. The heart usually is overactive. The first heart sound is normal and frequently followed by an ejection click, which echocardiographic studies have shown to coincide with maximal opening of the truncal valve. The second heart sound usually is loud and single. The occasional auscultatory or phonocardiographic observation of a split second sound in these patients with a single semilunar valve may be caused by delayed closure of some of the cusps of the abnormal truncal valve. An apical third heart sound often is present. A loud pansystolic murmur maximal at the lower left sternal border and radiating to the entire precordium most often is heard. An apical diastolic low-pitched murmur caused by increased flow across the normal mitral valve frequently is audible.

The patient with truncal valve insufficiency usually has a diastolic high-pitched murmur that is heard best along the left sternal border. A truly continuous murmur is uncommon in

truncus arteriosus and, when present, is usually suggestive of pulmonary artery ostial stenosis. Continuous murmurs are common in patients with pulmonary valve atresia/ventricular septal defect, however, where either a patent ductus arteriosus or systemic collateral arteries provide pulmonary blood flow. Because the differential diagnosis of truncus arteriosus includes this lesion, a continuous murmur is strongly suggestive of pulmonary atresia rather than of truncus arteriosus. Patients in heart failure may exhibit the additional signs of tachypnea, crepitant rales, hepatomegaly, and neck-vein distension.

Cyanosis is present, and clubbing of the fingers and toes may be seen in patients with decreased pulmonary blood flow caused by naturally occurring pulmonary artery stenosis, pulmonary artery banding, or pulmonary vascular disease. If there is no associated truncal valve insufficiency, the peripheral pulses and pulse pressure are nearly normal. The apical diastolic murmur often is not present. These patients are less likely to have signs and symptoms of cardiac decompensation.

Electrocardiographic Features

The electrocardiogram (ECG) usually shows a normal frontal plane QRS axis or minimal right-axis deviation. Generally, normal sinus rhythm is present, and the conduction times are not prolonged. Combined ventricular hypertrophy occurs frequently. Left ventricular forces are particularly prominent in patients with increased pulmonary blood flow. Left atrial enlargement also is common in this group. Patients with normal or decreased pulmonary flow may exhibit right ventricular hypertrophy only.

Radiologic Features

Typically, radiography of the chest shows moderate cardiomegaly and increased pulmonary vascular markings (Fig. 44.3). The aortic arch is right-sided in approximately one-third

Figure 44.3. Radiograph demonstrating typical features of truncus arteriosus in newborn with significant truncal valve insufficiency. Note the cardiomegaly and pulmonary vascular congestion.

of patients, and the combination of a right aortic arch and increased pulmonary vascularity is strongly suggestive of truncus arteriosus. Type I truncus arteriosus frequently is associated with a relatively superiorly located proximal left pulmonary artery, which usually can be distinguished on a frontal chest radiograph. A dilated truncal root is common. Although the pulmonary vascular markings typically are increased, variation in the pulmonary vascular pattern can be seen. In truncus arteriosus with unilateral absent pulmonary artery, the pulmonary vascular markings are markedly diminished on the side without the pulmonary artery (usually the left side). In addition, pulmonary vascular obstructive disease is common in patients with truncus arteriosus and is reflected in the chest radiograph by disproportionate enlargement of the central pulmonary arteries associated with accentuated tapering of the distal pulmonary arterial tree.

Echocardiographic Features

The use of 2-D, Doppler, and color Doppler echocardiography has greatly increased the ability to determine accurately the cardiac anatomy and, in most cases, the hemodynamics in truncus arteriosus (31,32). Subcostal windows are used to document abdominal visceral situs and atrial situs, in addition to the position of the cardiac apex. A single great vessel arising from the heart typically is seen from a subcostal image (Fig. 44.4A), and assessment of the atrial septum is performed best from this location as well. Subcostal windows provide additional views for evaluation of the truncal valve function, truncal root, and pulmonary artery branch anatomy. The parasternal long-axis view demonstrates the deficiency in the ventricular septum and the overriding great artery, with continuity between the truncal valve and the mitral valve. Slightly higher position in the parasternal long-axis view can be used to visualize the origin of the pulmonary trunk or branches (Fig. 44.4B). Further imaging is required to document the presence of a single arterial trunk and lack of a pulmonary outflow tract from the ventricle. High parasternal short-axis views will provide visualization of the pulmonary arteries arising directly from the posterolateral aspect of the truncal root, typically bifurcating into the right and left pulmonary arteries.

Persistence of a short MPA segment is seen in truncus arteriosus type I (Van Praagh type A1, Fig. 44.5). Separate origins of the pulmonary branches are seen in type II (type A2). When only one pulmonary artery is present, as in type III truncus (type A3), the remaining pulmonary artery origin must be documented, typically originating from the aortic arch or ductus arteriosus. The short-axis view is also useful in evaluating the anatomy of the truncal valve leaflets (number and morphology), as well as visualization of the coronary arteries and their origins, and the location and extension of the ventricular septal defect. Suprasternal notch imaging is critical for evaluation of the aortic arch anatomy, as interruption of the aortic arch may be associated with truncus arteriosus (type A4). Right-sided aortic arch also is common in truncus arteriosus and can be determined from short-axis imaging of the arch branching pattern. In addition, the pulmonary artery branches also can be visualized from the suprasternal notch, excluding any important branch stenoses (33).

Aortopulmonary window is in the differential diagnosis of truncus arteriosus and angiographically may be confused with truncus arteriosus. Echocardiographically, however, these two entities easily can be differentiated. Aortopulmonary window usually is not associated with a ventricular septal defect, and the right ventricular outflow tract and pulmonary valve are in the expected positions. These features usually are recognized easily by 2-D echocardiography. Moreover, in aortopulmonary window, use of a high parasternal short-axis view usually allows its direct visualization. In patients with truncal valve stenosis, Doppler echocardiography usually enables an estimation of this gradient. In patients with significant truncal valve insufficiency, the systolic Doppler gradient may overestimate the degree of valve stenosis owing to the volume of flow across the valve (2-D morphology must be correlated with the Doppler findings). Truncal valve incompetence also can be delineated and quantitated by Doppler technique; the color flow Doppler examination has been particularly helpful in this assessment. Doppler flow reversal in the abdominal descending aorta may be due to either pulmonary artery runoff, truncal valve insufficiency, or both. In the rare patient with a pulmonary artery band(s) in place, Doppler evaluation also permits assessment of the pressure gradient between the truncal root and the pulmonary arteries beyond the band.

Figure 44.4. A: Subcostal coronal view with anterior angulation in newborn with truncus arteriosus type I and moderately severe truncal regurgitation. Arrow indicates doming, thickened truncal valve; aortic root (Ao) continues anteriorly/superiorly. Origin of the pulmonary trunk indicated by the asterisk. L, left; LV, left ventricle; S, superior. B: High parasternal long-axis view in same newborn with truncus arteriosus type I, with the doming truncal valve (arrow) and posterior origin of the pulmonary trunk (asterisk). A, anterior; LA, left atrium; LV, left ventricle; RV, right ventricle; S, superior.

Figure 44.5. A: High parasternal short-axis view above the level of the truncal valve demonstrating posterior origin of pulmonary branches with very short main pulmonary artery segment (*short arrow*) and normal left and right pulmonary origins. Ao, aorta; L, leftward; P, posterior. B: Slightly higher short-axis view with same orientation as (A) illustrates central pulmonary artery confluence. RPA, right pulmonary artery; LPA, left pulmonary artery.

Truncus arteriosus may be diagnosed in utero with fetal echocardiography. The echocardiographer must be certain to identify the central MPA origin or proximal branch origin from the ascending truncal root to differentiate this condition from pulmonary atresia/ventricular septal defect. Associated interruption of the aortic arch also may be recognized in the fetus with truncus arteriosus. Severe truncal valve dysfunction (stenosis typically in combination with regurgitation) in utero may lead to fetal hydrops (30).

Cardiac Catheterization and Angiocardiography

With the introduction and advancement of accurate echocardiographic diagnosis and the advent of surgical correction during early infancy, before irreversible pulmonary vascular disease is a concern, diagnostic cardiac catheterization and angiography usually are unnecessary in the patient with truncus arteriosus (32). Rarely, the patient with truncus

arteriosus with associated interruption at the aortic arch or single pulmonary artery will need angiography to delineate aortic arch anatomy or the anatomy of the pulmonary arterial tree precisely. An example of a truncal root angiogram is seen in Figure 44.6. Magnetic resonance imaging (MRI), magnetic imaging angiography (MRA), or computed tomography (CT) scanning may be adequate to delineate this anatomy (see below).

Patients with truncus arteriosus are at risk of having pulmonary vascular obstructive disease develop at an early age, and this has driven the major impetus for early surgical correction (10). Even more uncommonly in this era, a patient with truncus arteriosus will still present initially beyond early infancy for consideration of surgical correction, and cardiac catheterization may be necessary to assess the status of the pulmonary vascular bed (22). Although direct measurement of pulmonary resistance is not possible, the calculated indirect value, obtained by dividing the mean driving pressure across the pulmonary bed (in mm Hg) by the total pulmonary flow

Figure 44.6. Anteroposterior (A) and lateral (B) views of truncal root angiogram in 10-month-old patient with truncus arteriosus, type I. index (in liters per minute per square meter), provides a reliable estimation of the status of the pulmonary arterioles.

Patients with truncus arteriosus who have two pulmonary arteries and a pulmonary arteriolar resistance >8 units m^2 are at higher operative risk than patients with resistances below that level (20,22). Among the group with resistances >8 units m^2 , late deaths were due to progression of pulmonary vascular obstructive disease with secondary severe pulmonary hypertension and right ventricular failure. Among the survivors of operation in the group with preoperative resistance <8 units m^2 , no late deaths occurred secondary to progressive pulmonary hypertension.

Fortunately, the trend toward early corrective surgery has reduced the number of patients who are inoperable because of pulmonary vascular obstructive disease. Our current policy is not to offer corrective surgery to patients with truncus arteriosus who have two pulmonary arteries and whose pulmonary arteriolar resistance is >8 units m^2 . The exceptions are children younger than 2 years of age whose resistance decreases to <8 units m^2 , when 100% oxygen is breathed or after administration of a pharmacologic vasodilator such as inhaled nitric oxide. In such young patients, surgery still may be offered if the parents are willing to accept a higher surgical risk because it is possible that the increased resistances may result from arteriolar or medial smooth muscle hypertrophy and vasoconstriction rather than advanced intimal occlusive disease. These changes potentially may be reversible, and such patients can be treated with pulmonary vasodilator therapy after surgical repair is undertaken.

Different criteria must be used to assess the feasibility of operation in patients with unilateral absence of a pulmonary artery (34). Severe pulmonary vascular disease is particularly likely to develop at an early age in patients with a single pulmonary artery (22,35). To achieve good surgical results in this subgroup, corrective surgery should be performed in the neonatal period. Even in patients who survive corrective operation, however, pulmonary vascular disease tends to progress postoperatively more often than it does in patients with

corrected truncus arteriosus who have two pulmonary arteries (35). This difference may be related to the fact that the entire cardiac output still must pass through one lung so that the rate of flow through each arteriole remains approximately double. This may be a potential stimulus for the progression of pulmonary vascular changes.

An accurate preoperative catheterization laboratory assessment of truncal valve insufficiency may be difficult because of contrast runoff into the pulmonary artery bed.

Magnetic Resonance Imaging

Cardiac MRI and MRA can provide additional noninvasive anatomic and hemodynamic information in the patient with truncus arteriosus (36,37). Visualization of the conotruncus and pulmonary artery anatomy is accomplished by multiple techniques, including black blood and white blood imaging techniques with gating, and with the use of gadolinium contrast-enhanced MRA (Figs. 44.7 and 44.8).

DIFFERENTIAL DIAGNOSIS

In infants with truncus arteriosus and increased pulmonary blood flow, the differential diagnosis includes the other congenital cardiac conditions that cause early heart failure and are associated with either mild or no cyanosis. Such malformations include ventricular septal defect, patent ductus arteriosus, aorticopulmonary window, pulmonary atresia with ventricular septal defect, and patent ductus arteriosus, or large collateral arteries, double-outlet right ventricle, univentricular heart, and total anomalous pulmonary venous connection. In truncus arteriosus with decreased pulmonary flow, other conditions to be considered include pulmonary atresia, tricuspid atresia, tetralogy of Fallot, univentricular heart with pulmonary stenosis, and double-outlet right ventricle with

Figure 44.7. pulmonary stenosis. Although certain physical findings, chest radiographic evidence, and electrocardiographic features may suggest the increased likelihood of a particular lesion, echocardiography is necessary to establish the diagnosis definitively.

NATURAL HISTORY

Although patients with truncus arteriosus occasionally survive to adulthood without surgery, the natural history of this condition is generally dismal. In one autopsy series, the mean age of death was 5 weeks. Another series reported a survival of only 15% beyond the age of 1 year. Death in infancy most commonly is caused by heart failure. In patients who survived the first 4 years, death may occur from heart failure, but more frequently it results from the complications of hypertensive pulmonary vascular disease and infective endocarditis.

Once severe pulmonary vascular disease is present (38), deterioration often is rapid, with severe morbidity and death frequently occurring in late childhood or early adolescence. This dismal natural history was the main factor that gave rise to the approach of early surgical repair that is now advocated for these patients.

TREATMENT

The diagnosis of truncus arteriosus, itself, is an indication for operation. Diagnosis ideally is made prenatally or soon after birth. Medical stabilization is performed in the intensive care unit, and operation with complete repair is preferred in

the first weeks of life. Delay of operation results in chronic ischemia of the hypertrophied ventricle, which is perfused by desaturated blood at a low diastolic perfusion pressure caused by runoff through the pulmonary arteries, and, when present, “aortic” insufficiency. This hazard of ventricular dysfunction may explain, in part, the observation that repair of truncus at 6 to 12 months of age is associated with mortality twice that for repair between 6 weeks and 6 months of age (10). Pulmonary vascular obstructive disease also can develop early, which provides additional impetus for correction in the first few months of life. Pulmonary vascular obstructive disease, no doubt, also is partly responsible for the increased surgical mortality in infants who undergo repair after 6 months of age.

The preferred operation is complete repair during the neonatal period. Although pulmonary artery banding may provide palliation for young patients with truncus arteriosus, there are well-documented risks and potential complications of banding for this condition. In addition, successful banding has not guaranteed that these patients will be good candidates for later correction (39). During the past 15 years, improved surgical techniques and postoperative care have made correction of truncus arteriosus during infancy possible at an operative risk less than that previously reported for banding.

SURGICAL CORRECTION

Successful definitive surgical correction in a patient with truncus arteriosus was first accomplished by McGoon et al. in 1967 (9). In the original operation, based on the experimental work of Rastelli et al. (40), continuity between the right ventricle and

the pulmonary arteries was established with an aortic homograft. Cryopreserved homograft tissue continues to be the conduit of choice for repair of this defect in early infancy (41).

The early and late results experienced by the initial 92 patients who had correction at the Mayo Clinic were reported in 1977 (20). Although overall hospital mortality was 25%, the operative mortality decreased to 9% in the 33 patients operated on during the last 2.5 years of this early series. Since that time, an operative mortality of 5% was achieved in patients without severe associated abnormalities who subsequently have undergone correction of truncus arteriosus. In 1984, Ebert et al. (10) reported results of 100 infants repaired prior to 6 months of age, emphasizing the importance of early repair to prevent the development of pulmonary vascular obstructive disease. Early mortality was 11%. At this time, the importance of complete repair in early infancy to prevent the development of pulmonary vascular obstructive disease was also emphasized.

During the last three decades, there has been great progress in the surgical management of infants (42). In the current era, excellent results have been obtained with corrective operation during infancy (42–48). In patients who undergo successful correction during early infancy, the small right ventricular to

pulmonary artery conduit eventually must be replaced with a larger one, but reoperation for conduit replacement alone carries a low risk (49–52). A 1993 late follow-up of 137 patients with truncus arteriosus corrected at the Mayo Clinic between 1967 and 1992 showed no perioperative deaths in 39 patients who underwent reoperation for isolated conduit replacement. One death occurred in 15 patients who had isolated conduit replacement performed elsewhere (53).

Although techniques of repair that do not include an extracardiac conduit also have been described (54), most surgeons prefer a valved conduit when complete repair is performed because of the presence of pulmonary hypertension. Techniques for conduit replacement have evolved over the last two decades (49,55). It is our current preference to use the autologous tissue reconstruction (“peel operation”) to reconstruct the right ventricular outflow tract when conduit replacement is required (Fig. 44.9). The technique includes placement of a prosthetic roof (usually bovine pericardium) over the fibrous bed of the explanted conduit with insertion of a prosthetic valve (usually bioprosthesis). Early mortality has been low for conduit replacement, in our experience, even after multiple conduit revisions (49,55). Early mortality was

Figure 44.9. Technique of peel operation. A: Illustration depicting the obstructed extracardiac Dacron conduit being removed from the thick fibrous peel that surrounds it. Illustrations of the pericardial roof constructed and sewn to the lateral edges of the fibrous tissue bed. The routinely inserted porcine bioprosthesis is positioned either distally (B) or proximally (C), depending on the cardiac diagnosis, the anatomy, and the discretion of the operating surgeon (see text). Ant, anterior; Ao, aorta; lat, lateral; Pul, pulmonary; RV, right ventricle; SVC, superior vena cava. (Reprinted from Dearani J, Danielson G, Puga F. Late follow-up of 1095 patients undergoing operation for complex congenital heart disease utilizing pulmonary ventricle to pulmonary artery conduits. *Ann Thorac Surg* 2003;75:339–411, with permission from the Society of Thoracic Surgeons.)

Figure 43.10. Postoperative aortic root angiogram from a 7-year-old patient with severe aortic valve regurgitation following truncal (aortic) valvuloplasty in infancy at the time of complete repair. Anteroposterior (A) and lateral (B) views show dense opacification of the left ventricle following injection in the ascending aorta. Ao, aorta; LV, left ventricle.

2% but was 0% for isolated conduit replacement. Overall survivorship free of reoperation for the peel reconstruction at 10 and 15 years was 90.7% and 82%, respectively.

The presence of a regurgitant truncal valve almost always is amenable to various repair techniques, and replacement is rarely, if ever, done in the neonatal period. Numerous authors have described various truncal valvuloplasty techniques (43,56–62). Frequently used techniques include suturing of the prolapsing leaflet to adjacent leaflets. The prolapsing leaflet usually is thickened and adjacent leaflet edges also are thickened, which facilitates suture placement. The tops of the commissures often are splayed from dilation of the sinotubular junction. This can be corrected by wedge excisions of the aorta. If recurrent truncal valve incompetence occurs, our policy is to repair or replace the truncal valve at the time of reoperation for conduit replacement.

Late results following complete repair are determined by the degree of truncal valve regurgitation and the need for conduit replacement. The need for truncal valve repair at the time of complete repair is low (63). If reoperation is required for truncal valve regurgitation, intermediate-term results favor repair of the truncal valve (43,62). Serial echocardiographic examinations are essential during lifelong follow-up. Recurrent truncal valve regurgitation may necessitate repair or replacement at a subsequent operation (Fig. 44.10). In our follow-up of 137 patients with truncus arteriosus who were operative survivors in our initial 25-year experience, no one underwent truncal valve replacement when trivial or no truncal valve incompetence was present at the time of correction. In patients who had mild, moderate, or severe truncal incompetence, the eventual need for truncal valve replacement was high. The difference between the two groups was highly significant ($p < 0.001$, Fig. 44.11).

Figure 44.11. Probability of late aortic (truncal) valve replacement after corrective operation: late survivors according to degree of assessed immediate post correction aortic valve insufficiency. All reoperations for valve replacement were in patterns judged to have mild, moderate, or severe insufficiency.

Figure 44.12. Postoperative right ventricular angiogram from the same 7-year-old patient as in Figure 44.10 who underwent truncus arteriosus repair as neonate, followed by re-replacement of the original pulmonary homograft in the first year of life. Anteroposterior (A) and lateral (B) views show heavily trabeculated right ventricle (RV) with diffuse narrowing of the heterograft conduit. In addition, there is mild proximal right pulmonary artery narrowing seen in the AP projection (arrow). No significant tricuspid regurgitation is seen.

The primary late problem related to extracardiac conduit operations is the need for conduit replacement because of somatic growth or progressive deterioration and calcification of the conduit (Fig. 44.12). Numerous reports have focused on issues of conduit size, valve degeneration, and conduit degeneration (49–52,64–80). Late outcome of homograft (41,49,81–84) and prosthetic (49,85,86) conduits has been reported with variable results. Our attempt to reduce the incidence of late conduit failure was the construction of an autologous tissue conduit, with or without a valve. Advantages of this technique include an autogenous floor with a pericardial roof that does not form obstructive peels, and the diameter of the pathway can be as large as desired, allowing a large bioprosthetic valve to be inserted. We have examined the freedom from reoperation for conduit failure in an age-matched group of patients who have received a Hancock conduit, a homograft conduit,

and a valved peel reconstruction (Fig. 44.13). The peel operation had statistically significant better freedom from reoperation compared with the homograft ($p = 0.001$). Although the peel operation had more favorable durability than the Hancock conduit, this did not reach statistical significance ($p = 0.19$) owing to the small numbers in the peel operation group at late follow-up. Percutaneous pulmonary valve therapy is now an alternative and complementary therapy for the postoperative truncus patient with a failing conduit (87–90).

The search continues for the ideal extracardiac conduit. Although the need for reoperation is inevitable for most patients, the risk of reoperation is low and most patients enjoy a good quality of life. Presently, the peel operation provides the most favorable freedom from reoperation and is our procedure of choice when conduit replacement is required.

Figure 44.13. Survival freedom from reoperation for conduit failure in an age-matched population, stratified according to conduit type (peel operation vs. Hancock, $p = 0.19$; peel operation vs. homograft, $p = 0.0001$). (Reprinted from Bermudez C, Dearani J, Puga F. Late results of the peel operation for replacement of failing extracardiac conduits. *Ann Thorac Surg* 2004;77:881–888, with permission from the Society of Thoracic Surgeons.)

CARE OF THE ADULT PATIENT WITH REPAIRED TRUNCUS ARTERIOSUS

The adult patient with repaired truncus arteriosus will require lifelong follow-up by experienced adult congenital heart disease cardiologists. Truncus arteriosus is considered to be a complex form of congenital heart disease so that care of these patients in an experienced regional center is preferred (91). The primary issues for these patients include long-term function of the right ventricular-to-pulmonary artery conduit and of the truncal (aortic) valve, the potential for branch pulmonary artery abnormalities, development of significant tricuspid regurgitation, and aortic root dilation. In addition, genetic testing should be considered in patients who have not had evaluation for 22q11 microdeletion syndrome (92).

Follow-up of such patients generally is performed every 1 to 2 years, and should include a thorough clinical examination, chest radiogram, and ECG. Echocardiography is recommended to assess the function of the right ventricle-to-pulmonary artery conduit and valve, paying close attention to stenosis and/or regurgitation. A peak gradient of over 50 mm Hg in the pulmonary conduit generally is considered to be indicative of severe stenosis, as is a right ventricular systolic pressure over 75 mm Hg (91). There may be evidence of decreased right ventricular function and/or an increase in the degree of tricuspid regurgitation concurrent with a deterioration of conduit valve function. One should assess the degree of truncal or aortic valve insufficiency and consider replacing this valve if significantly incompetent. Aortic root dilation may occur. Pulmonary artery branch abnormalities may be difficult to image with echocardiography, so that ancillary imaging techniques such as cardiac MRI often are helpful in the assessment and management of these patients (93).

Cardiac catheterization generally is reserved for assessment of abnormalities detected by noninvasive imaging techniques and may involve additional interventions, such as balloon angioplasty of pulmonary branch stenosis or implantation of endovascular stents in the branch pulmonary arteries. Percutaneous implantation of a bioprosthetic pulmonary valve now is available for appropriate patients (88–90). Any surgical intervention should be carried out in an institution that specializes in the care of adults with congenital heart disease and performed by a surgeon trained in congenital heart disease (91).

LONG-TERM ISSUES

In summary, patients with repaired truncus arteriosus will need lifelong cardiovascular follow-up. Infective endocarditis precautions are warranted. Primary issues that will require attention, ongoing evaluation, and potentially further treatment after neonatal repair include truncal valve dysfunction (stenosis and/or insufficiency), function of the pulmonary homograft/conduit in the right ventricular outflow tract, and the development of branch pulmonary artery stenosis. Left and right ventricular function, both systolic and diastolic, must be evaluated in an ongoing fashion. Echocardiography and cardiac MRI/MRA are useful tools for ongoing noninvasive evaluation of the patient with repaired truncus arteriosus (37). Seamless transition from the pediatric cardiologist to the adult congenital heart disease specialist is clearly warranted as this patient group ages.

Anatomical and Functional Mitral Valve Abnormalities in the Pediatric Population

Andrew S. Mackie ■ Jeffrey F. Smallhorn

This chapter deals with mitral valve (MV) abnormalities that are encountered in the pediatric population. We include abnormalities of the morphologic MV in corrected transposition, but exclude abnormalities in the setting of a univentricular atrioventricular connection, left side atrioventricular valve in atrioventricular septal defect, and MV abnormalities in rheumatic heart disease. As well, we exclude hearts with hypoplastic left heart syndrome, as these patients follow a different clinical pathway. Although some MV abnormalities occur in isolation, many are part of a spectrum of left-sided congenital abnormalities. If missed, these associated lesions often have profound implications with regard to patient outcome, and hence a high index of suspicion is essential when evaluating a patient with abnormalities of the MV.

Although clinical signs and symptoms are important, noninvasive imaging, in particular echocardiography, is the current cornerstone to detailed anatomical and physiologic assessment and subsequent management implications of congenital MV disease. Three-dimensional echocardiography provides novel anatomical and functional information above and beyond 2-D echocardiography and is emphasized throughout this chapter.

MITRAL VALVE DEVELOPMENT

Following rightward looping of the heart tube, the atrioventricular junction becomes prominent around the 25th day of gestation (1,2). The future left ventricle (LV) supports the larger part of the circumference of the atrioventricular canal by the end of the 5th week. The atrioventricular canal is occupied by the inferior and superior endocardial cushions that fuse during the 6th week, producing separate right and left atrioventricular junctions. Parts of these fused cushions remain on the left side of the muscular septum, forming the scaffold of the anterior or aortic leaflet of the MV.

The normal MV proceeds when the aorta becomes committed to the LV, permitting the development of fibrous continuity between one of the leaflets of the MV and two of the leaflets of the aortic valve. Initially, there is a cleft at the site of fusion of the superior and inferior cushions within the LV. The mural leaflet or posterior leaflet is formed by protrusion and growth of a sheet of atrioventricular myocardium into the ventricular lumen, with subsequent formation of valvar mesenchyme on its surface (3). The myocardial layer is then removed by apoptosis. The aortic leaflet of the MV develops from the mesenchyme of the superior and inferior atrioventricular cushions and is never attached to, or supported by, the myocardium apart from its attachment to the papillary muscles. The inferior quadrants of the left atrioventricular junction expand involving growth of the parietal wall of the LV, with comparable growth of the lateral cushion. This results in the lateral cushion occupying

two-thirds of the circumference of the developing mitral valvar orifice, hence the larger mural or posterior leaflet that is seen during clinical or pathologic assessment. The papillary muscles develop from compacting columns in the trabecular layer of the ventricular muscle. Importantly, the MV develops and functions as a unit, which has profound implications during life. With the advent of 3-D echocardiography, we are moving away from thinking of the MV as independent units, but rather as units that interact with each other and with the left ventricular myocardium.

Reciprocal signaling between the endocardial and myocardial cell layers in the cushion is mediated in part by members of the TGF- β family, and induces a transformation of endocardial cells into mesenchymal cells. Sox 9 is activated when endocardial cells undergo mesenchymal transformation and Sox-9-deficient mesenchymal cells fail to express ErbB3, which is required for proliferation of the cells within the endocardial cushions. The mesenchymal cells migrate into the cushions and differentiate into the fibrous tissue of the valves. Several genes play a role in formation of the valvar leaflets, with signaling and downstream activation dependent on the NF-AT family of transcription factors. Absence of any of these genes results in fatal defects of valvar formation (4–6).

INCIDENCE OF MITRAL VALVE ABNORMALITIES

Congenital MV abnormalities are rare. Congenital mitral stenosis (MS) accounts for 0.6% of congenital heart disease (CHD) in postmortem studies and 0.21% to 0.42% when examined in clinical series (7). Isolated congenital MV regurgitation is even rarer and indeed if encountered should be considered as potentially being secondary to another process such as rheumatic fever or in the younger patient, anomalous left coronary artery from the pulmonary artery (8). The male to female ratio of congenital MS is of the order of 1.5:1. It is important to consider associated MV pathology in any child presenting with a left-sided obstructive lesion, such as coarctation of the aorta or aortic valve stenosis. As well, MS may be associated with many other congenital lesions. Therefore, assessment of MV morphology and function should be part of the evaluation of all patients with CHD.

MITRAL VALVE MORPHOLOGY AND FUNCTION

Although the morphologist has previously been the master in this area, that role has now fallen to the echocardiographer, who can evaluate both morphology and function.

MITRAL ANNULUS

The mitral annulus is mostly a muscular structure that is attached to the left atrium by fibrous connections. Three-dimensional imaging has demonstrated that it is saddle shaped (9), with two high and two low points (Fig. 45.1A). The high points are at the site of aortic–mitral continuity and at the posterior aspect of the valve, while the two low points are along the lines of the commissure between the aortic and mural leaflets. The region of the mitral annulus that is not

muscular is the site of aortic–mitral fibrous continuity. This is an important component, since changes in the mitral annulus during the cardiac cycle are heterogeneous, such that the outlet maintains maximum dimension during contraction to prevent any impediment to flow (10,11).

The saddle shape of the mitral annulus has significant implications with regard to leaflet stress. If the annulus is more planar in shape, this increases leaflet stress, which has negative implications with regard to MV function (12,13). This in part explains why standard MV rings fail, as they do not address the primary problem, and flatten the MV annulus as well.

Figure 45.1. A: Schematic diagram demonstrating the saddle shape of the mitral annulus with two high points, one at the aortic–mitral continuity end and the other posterior. The two low points are along the commissure lines of the anterior and posterior leaflets. The maximum bending of the MV occurs along the commissure line. A, aortic leaflet; AL, anteriolateral; LV, left ventricle; P, posterior or mural leaflet. B: This montage demonstrates the normal features of the MV, as seen by 3-D echocardiography. Note the scalloped appearance of the posterior or mural leaflet. The commissures are seen in the image. Three-dimensional echocardiography shows the true features of the MV with its undulations that are readily appreciated in this *en face* view. The upper panel is taken in systole, while the lower one is in diastole. AL, aortic or anterior leaflet; AOV, aortic valve; PL, posterior or mural leaflet. C: These images demonstrate a normal MV seen in a 3-D and an MPR (multiplane reformatting) mode obtained from a full-volume data set. The upper two images are the 2-D views of the MV, taken at right angles to each other. The lower right hand image shows the reconstructed image of the valve and the two planes (red and green) can be seen. The lower left hand panel shows the MV from below. The commissures are well seen, as are the two leaflets. Note the detail in the 3-D image that is lacking in its 2-D counterpart. AL, aortic or anterior leaflet; AO, aorta; LA, left atrium; LV, left ventricle; LVOT, left ventricular outflow tract.

Starting at end diastole and with atrial contraction the annulus begins to contract, attaining its smallest area just before ventricular systole, presumably to aid in leaflet closure. During midventricular systole there is a dominant inward motion of the annulus in an anterior–posterior direction. This helps maintain an oval shape just when the orifice area is at its greatest, with the added advantage of helping to keep the leaflets together. During ventricular contraction, the annulus descends with a gradual increase in annular area, height, and bending angle. This reaches its maximum at end systole and during the period of isovolumic relaxation. With rapid ventricular filling there is a rapid reduction in MV area (14–17), more so in children, which may be related to their superior ventricular relaxation (14–17). These changes are most likely related to the torsional deformation of the LV from base to apex, demonstrating the importance of thinking of the MV as one unit, with important interactions with the LV.

MITRAL VALVE LEAFLETS AND SUPPORTING APPARATUS

The normal MV has two leaflets, the anterior or aortic and the posterior or mural (Fig. 45.1B). The anterior leaflet is in fibrous continuity with the noncoronary cusp of the aortic valve and hinges from the annulus with support at two commissures by the anterior and posterior papillary muscles (1,18). The anterior leaflet has been arbitrarily divided into

three components, A1 to A3, which is a useful description for both the echocardiographer and the surgeon. The mural or posterior leaflet is anchored along the parietal part of the left atrioventricular junction. As with its anterior counterpart, this is divided into three components, P1 to P3. As with the anterior leaflet, it is supported by the two papillary muscles. The posterior or mural leaflet frequently has a series of scallops, which are supported by chordal structures (Fig. 45-1B,C).

Three-dimensional echocardiography has provided the ability to assess not only the morphology but also the dynamic changes that are seen in the MV. This technique emphasizes that the leaflets are not flat, but consist of a series of undulations, which are in part related to the chordal attachments (13) (Fig. 45-1A). There are several chordal support mechanisms that can be appreciated in pathologic specimens (19), as well as by real-time 3-D echocardiography. The strut chordae insert into the undersurface of the anterior leaflet and in part result in the appearance of a series of peaks and valleys in the anterior leaflet when seen in real time from the left atrial view (Fig. 45.2A). These chordae run onto the belly of the leaflet, whereas the rough zone chordae insert into the tip of the anterior leaflet (Fig. 45.2A). These latter chordae are responsible for preventing leaflet prolapse. The strut chordae are important in situations of ischemic MV regurgitation where they are displaced, resulting in leaflet tethering and regurgitation (20). Next, there are commissural chords, which by definition support the two MV commissures, while the cleft chordae support the scallops of the posterior or mural leaflet. When viewed from above by 3-D echocardiography during systole,

Figure 45.2. A: These figures demonstrate the chordal structures of the MV in a specimen, as well as by 3-D echo. Note the thicker strut chordae that are indicated by the *black arrow*. These insert into the belly of the aortic leaflet of the MV. The thinner rough zone chordae insert into the edges of the leaflet. LA, left atrium; LV, left ventricle; PM, papillary muscle; RZC, rough zone chordae; SC, strut chordae. B: This montage shows the normal papillary muscle arrangement of the MV. The image on the left demonstrates the anterior papillary muscles with mitral chordal insertion. The image on the right shows the posterior papillary muscle and shows how it is blended in the posterior wall of the LV. APM, anterior papillary muscle; LA, left atrium; LV, left ventricle; PPM, posterior papillary muscle.

the leaflets appear to be a series of peaks and valleys, the coaptation of which prevents regurgitation (13). The zones of coaptation of the leaflets roll over each other, providing the maximum area of contact, which maintains valve competence. It is when pathologic processes disturb this relationship that regurgitation is seen. Pathologic specimens and surgical inspection, along with saline testing of the valve provide a sub-optimal assessment of the functional nature of the MV; 3-D echocardiography overcomes this limitation (21).

The two papillary muscles are evenly placed such that they maintain constant tension on the leaflets throughout systole (Fig. 45.2B). The angle between the papillary muscle tips and the mitral annulus is about 70 to 80 degrees, as determined by 3-D echocardiography. This is achieved by the ability to map the coordinates of all of the components of the MV throughout the cardiac cycle and relate them to each other. This papillary muscle angle does not change throughout the cardiac cycle, despite the influence of ventricular contraction and torsion of the LV. The chordae fan out as they insert into the leaflets, but the direction of pull on the leaflets is relatively vertical, avoiding tension on the leaflets. The papillary muscle morphology is also variable, in particular with regard to the number of heads. The papillary muscles are derived from left ventricular myocardium and blend in with the wall of the LV, playing an important role in maintaining normal left ventricular function (Fig. 45.2B). Indeed if they are removed during valve replacement, then this results in left ventricular dysfunction (22).

MITRAL VALVE PATHOLOGY: AN INTEGRATED MORPHOLOGIC AND HEMODYNAMIC APPROACH

Although it is tempting to divide pathology into regurgitant and stenotic lesions, this is artificial, since congenital MV

abnormalities can result in both. We therefore describe the types of pathology and their echocardiographic appearances together.

Mitral Valve Dysplasia and Hypoplasia

In MV dysplasia, the leaflets are thickened, the interchordal spaces obliterated, and the papillary muscles deformed (7,23,24). The valve often shows global hypoplasia and is the most common lesion associated with isolated congenital MS, though this may occur in conjunction with regurgitation. The free edges of the dysplastic leaflets are thickened and rolled. Therefore, when viewed as a functional unit, the thickened leaflets and obliterated interchordal spaces result in tethering and deficient zones of coaptation. These features are readily appreciated by 3-D echocardiography, both from a left atrial and left ventricular view (Fig. 45.3A,B). As well, additional images can be obtained by cropping the heart from above, which demonstrate the MV and its support apparatus. This is of particular value for imaging the chordal apparatus, as they are imaged in the axial plane that provides optimal resolution. The left ventricular view is of particular importance for imaging the commissures, because they are imaged more reliably from below than from the left atrial view. This is due to the fact that the normal mitral leaflets billow toward the left atrium, just as a parachute does when seen from the sky.

With the addition of color Doppler, sites of mitral regurgitation (MR) can be identified and related to valve pathology (Fig. 45.3A). It is possible to image the vena contracta, which represents the *en face* view of the regurgitant jet. The area of this jet correlates well with absolute volume regurgitation, providing a semiquantitative assessment of the degree of regurgitation (Fig. 45.4A). As well, it provides an accurate road map to the location of the regurgitation, providing vital information for the surgeon when contemplating repair. With the addition of pulsed or continuous wave Doppler the hemodynamic mean gradient can be determined. Recall that this is

Figure 45.3. A: These images are from a case with MS due to shortened chordae and thickened leaflets. The 3-D image from below shows the thickened leaflets with shortened chordae. Note the orifice of the MV. The image on the right is a 2-D Doppler and shows the turbulent jet through the valve. LV, left ventricle; LVOT, left ventricular outflow tract; PM, papillary muscle. B: This montage is from a case with MV stenosis due to thickened chordae, with virtual fusion of the anterior papillary muscle to the leaflets, as seen by the lower right hand 3-D echo. The upper left hand image shows the 2-D appearance of the anterior papillary muscle and leaflet. The restrictive functional orifice is clearly seen in the lower right hand panel (black arrow). LV, left ventricle; PM, papillary muscle.

Figure 45.4. A: This montage is from a case with a tethered mural leaflet of the MV, associated with thickening of both that leaflet and its aortic counterpart. The upper left image is viewed from front, looking down on top of the MV. Note that it is difficult to see separate chordae. The lower left hand picture shows the vena contracta from the MV regurgitation. Note that the relationship of this to the valve can be appreciated from this image. The upper right hand picture views the MV from the left ventricular aspect and shows the tethering of the mural leaflet as indicated by the *black arrows*. The lower right hand picture is a view of the MV from above at a level just below the mitral annulus. The mitral orifice and the thickened leaflets can be seen, as well as the tethering of the mural leaflet (*black arrow*). AL, aortic leaflet; AO, aorta; LVOT, left ventricular outflow tract; ML, mural leaflet; PM, papillary muscle; VC, vena contracta. B: This is from the same case as Figure 45.4A and shows the 2-D echo appearance of the tethered mural leaflet, as well as a 3-D long-axis view of the MV. The upper left hand image is taken in diastole and the right one in systole. The *black arrow* points to the annulus of the MV and shows that during systole the leaflets are tethered below the annulus. This appearance cannot be appreciated in 2-D images. LA, left atrium; LV, left ventricle.

directly related to cardiac output, with an underestimation in states of low output. Unfortunately, in the majority of children, it is not possible to calculate a pressure halftime that can provide an absolute valve area in adults.

Dysplasia of the Posterior or Mural Leaflet

Occasionally, a young child is seen who has significant MV regurgitation secondary to dysplasia of the posterior or mural

leaflet (25). The leaflet is invariably tethered by shortened chordae, preventing normal coaptation with the anterior leaflet (Fig. 45.4A,B). The regurgitant jet invariably extends along the total length of the valve orifice and may respond to surgical repair by leaflet extension. Three-dimensional echocardiography provides optimal imaging of this entity, as well as an accurate assessment of the severity of regurgitation. Although the mural leaflet is tethered, the aortic leaflet of the MV is usually thickened (Fig. 45.4A,B).

Figure 45.5 A: This montage shows a mild case of supramitral stenosis, which is more difficult to appreciate in the 2-D image in the left hand panel, compared to the 3-D image on the right viewed from the left atrium. B: The color Doppler image on the right shows that the flow acceleration is starting just above the annulus, consistent with supravale stenosis. LA, left atrium; LV, left ventricle; SMR, supramitral ridge.

Supravale Mitral Stenosis

Although this is often considered as a separate entity (Fig. 45.5A,B), it invariably coexists with associated abnormalities of the leaflets and subvalve apparatus (26,27) (Fig. 45.6). Therefore, in the majority of cases, surgical intervention does not cure the problem, but simply provides some relief of the associated stenosis. The membrane starts at the annulus of the MV, thus differentiating it from cor triatriatum, which sits above the left atrial appendage. It may or may not be circumferential and in some cases extends into the orifice of the MV, providing the appearance of subvalve MS. Physiologically, it usually results in MS, the hemodynamic consequence that can be determined by a Doppler assessment of the MV in conjunction with an assessment of pulmonary artery pressure from the tricuspid regurgitation and/or pulmonary insufficiency jets. This entity therefore has a physiologic impact on the mitral annulus, as well as the leaflets and subvalve apparatus.

Mitral Arcade

This is a rare entity, however one that has a significant impact on outcome. The morphologic and echocardiographic features are of muscularization of the chordal apparatus, such that it is difficult to differentiate between the leaflets, chordae, and their supporting papillary muscles (Fig. 45.7). The functional result is often regurgitation, which is due to a tethered valve with deficient zones of leaflet coaptation. This lesion usually presents early on in life and invariably results in a poor outcome (28,29).

Figure 45.6. This is from a case with supramitral valve stenosis and associated significant pathology of the leaflets and subvalve apparatus of the MV. The upper left hand and lower right hand panels show the ring as indicated by the black arrows. The upper left hand and lower right hand demonstrate the thickened leaflets and chordae. The upper right hand panel shows the orifice of the MV as seen from the left atrium. AO, aorta; LA, left atrium; LV, left ventricle; LVOT, left ventricular outflow tract; PM, papillary muscle; SMR, supramitral ridge.

Figure 45.7. This montage shows a specimen with a mitral arcade with muscularization of the subvalve apparatus and a 3-D echocardiogram showing similar features, but from a different case. LA, left atrium; LV, left ventricle; PM, papillary muscle.

Cleft Mitral Valve

This involves the anterior or aortic leaflet of the MV and varies in degree with some hearts having a complete cleft, whereas in others it involves only the tip of the leaflet. The cleft points towards the left ventricular outflow tract, which differentiates it from that seen in an atrioventricular septal defect (30–35) (Fig. 45.8). The supporting papillary muscles are in the normal location, again which differs from an atrioventricular septal defect where the posterior muscle is rotated laterally (36). MV regurgitation is usually seen when the edges of the cleft are unsupported by chordae. In other cases, the edges of the cleft are supported by chordae without evidence of associated MV regurgitation (Fig. 45.9). The chordae invariably insert into the crest of the interventricular septum, while in other cases they may straddle an anterior ventricular septal defect. The degree of MV regurgitation is usually dictated by the extent of the cleft, with greater severity in those where the cleft extends along the whole length of the anterior leaflet. While 2-D echocardiography is helpful in the diagnosis, it does not permit a complete evaluation of the

Figure 45.8. These images are from a case with a cleft in the anterior leaflet of the MV, with the cleft pointing toward the left ventricular outflow tract. The upper left hand image is a 3-D echocardiogram seen from the left atrium, with the cleft being indicated by the *black arrow*. The upper right hand picture is from the same case, but viewed from the left ventricular aspect. The lower two images are from the same case, with the left one showing the papillary muscle distribution and the right one the 2-D appearance of the cleft. The extent of the cleft is better appreciated in the 3-D images. AL, aortic leaflet; AO, aorta; APM, anterior papillary muscle; LV, left ventricle; ML, mural leaflet; PPM, posterior papillary muscle; RV, right ventricle.

Figure 45.9. These images are from a case with postoperative tetralogy of Fallot and an eccentric MV cleft associated with accessory chordal apparatus that inserts from the cleft into the interventricular septum. The eccentric cleft is indicated by the *asterisk*. AL, aortic leaflet; AO, aorta; LA, left atrium; LVOT, left ventricular outflow tract; ML, mitral leaflet; RV, right ventricle.

extent of the cleft: 3-D echocardiography does. Imaging the MV from the left atrial or left ventricular aspect provides a complete assessment of the extent of the cleft, the supporting apparatus, and the commissures. The site and degree of regurgitation can be determined by an *en face* view of the valve using color Doppler.

Parachute Mitral Valve

Although cases exist with a solitary papillary muscle, the initial description by Shone (26) included hearts with a dominant papillary muscle, which supported most of the chordal apparatus and a smaller secondary rudimentary muscle. The presence of a parachute MV does not infer stenosis or regurgitation, as medium-term data would suggest that many require no intervention (37). In general, it is the associated leaflet dysplasia and chordal tethering that result in valve failure. This entity is readily recognized by 2-D echocardiography; however, its 3-D counterpart permits a more detailed assessment of the valve leaflets and chordal apparatus.

Double-Orifice Mitral Valve

This entity is seen more frequently in hearts with an atrioventricular septal defect; however it is occasionally encountered in an otherwise normal heart (38,39). In this setting, it is more common for each orifice to be supported by chordal apparatus and papillary muscle (Fig. 45.10A). This may be discovered as an incidental finding during an echocardiogram for another reason, while in other cases one of the functional orifices is regurgitant. These valves are rarely stenotic and in most cases never require any intervention. In general, this entity is readily recognized by both two and three-dimensional echocardiography. In some instances, one of the orifices is

imperforate, and the supporting tension apparatus can be appreciated from the left ventricular aspect (Fig. 45.10B).

Ebstein's-Like Anomaly of the Mitral Valve

This is a rare entity that involves displacement of the posterior or mural leaflet without thinning of the atrialized portion of the LV.

The Mitral Valve in Corrected Transposition

Although the major atrioventricular valve pathology involves the morphologic tricuspid valve, abnormalities of the MV are encountered fairly frequently (40). It is important to recognize these abnormalities, as they can have a profound effect on outcome when a double switch or atrial switch and Rastelli pathway is chosen. There may be MV leaflet dysplasia, multiple papillary muscles, an associated cleft, or a straddling MV (Fig. 45.11A,B). Three-dimensional echocardiography provides superior evaluation of the morphologic MV. The cleft, shortened chordae, and multiple papillary muscles are readily identified. In some cases, the valve is competent at presentation; however, when an anatomical repair is performed, the MV is unable to accommodate the associated systemic pressure. Unlike the normal MV that can cope with left ventricular dilation in the setting of normal left ventricular function many of these valves cannot due to the pathologic abnormalities mentioned above.

Straddling of the Mitral Valve

This is an important lesion to identify and invariably occurs in hearts with an abnormal ventriculoarterial connection,

Figure 45.10. A: These two images are from a double-orifice left atrioventricular valve, where both orifices are of a similar size. The 3-D image is from the left ventricular aspect. OR, orifice; LVOT, left ventricular outflow tract; RV, right ventricle. B: These images are from a double-orifice MV with an imperforate anterior orifice. The 2-D echo images on the left show the large posterior orifice and what appears to be a large separate anterior papillary muscle. The upper right hand panel is a 3-D image from below and shows the main orifice indicated by the *asterisk*, and the tension apparatus that supports the imperforate anterior orifice. The lower right hand panel views the MV from above and shows the imperforate anterior orifice indicated by the *black arrow*. MV, mitral valve; RV, right ventricle.

in particular ventriculoarterial discordance or double outlet right ventricle with an anterior aorta. The aortic or anterior leaflet is always involved with chordal apparatus from that leaflet having variable attachments within the right ventricle. In some instances, they insert into the crest of the interventricular septum while in others, they insert into a papillary

muscle on the proximal or distal interventricular septum (Fig. 45.12A,B). Of note, there is invariably an associated cleft in the MV with an eccentric orifice, pointing more toward the ventricular septal defect. The MV is usually competent due to the chordal support; however, recognition is important, because if the chordae are inadvertently cut during repair, the

Figure 45.11. A: This montage is from a case with corrected transposition after a double switch. There is significant MV regurgitation that is seen in the right hand color Doppler panel. The left hand panel shows the thickened leaflets, but the precise mechanism is unclear. MLV, morphologic left ventricle; MRV, morphologic right ventricle; PVA, pulmonary venous atrium. **B:** This montage is from the same patient as in Figure 45.11A. This shows the 3-D appearance of the morphologic MV. The image on the left shows the two atrioventricular valves from above during systole, while the one on the right shows the MV from below. The MV is trileaflet due to a cleft in the anterior leaflet. The *black asterisk* indicates the three components of the MV. AO, aorta; MLV, morphologic left ventricle; MMV, morphologic MV; MTV, morphologic tricuspid valve.

Figure 45.12. A: This montage shows a straddling MV as seen by two and three-dimensional echocardiography. The two lower images show the mitral chords inserting into a papillary muscle; however, the precise location is unclear. The upper right hand image is similar to the upper left one, but with slight angulation to show the anterior muscular ventricular septal defect with the chordae from the MV inserting into it. LA, left atrium; LV, left ventricle; PM, papillary muscle; RV, right ventricle; VSD, ventricular septal defect.

Figure 45.12. (Continued) B: This is from the same case as Figure 45.12A and shows the anterior muscular ventricular septal defect, as well as a second smaller perimembranous defect. The image on the left is with partial cropping of the heart, while the one on the right views the ventricular septal defect in front from the right ventricle. The precise location of the papillary muscle to which the MV is attached in the right ventricle is seen. MVSD, muscular ventricular septal defect; PM, papillary muscle; PMVSD, perimembranous ventricular septal defect; RV, right ventricle; TV, tricuspid valve.

valve will become regurgitant. Although 2-D echocardiography has superior temporal resolution making identification of fine chordal structures more accurate, inferior spatial resolution can impede precise location of the abnormal chordae. Three-dimensional echocardiography, by combining the multiplanar reformatting (MPR) mode, with volume rendering overcomes this limitation. The MPR mode permits navigation through the full-volume data set, making it possible to relate the chords to their anatomical location (Fig. 45.13). As the MV and its straddling chords insert in an anterior location, they are readily identified in a full-volume data set obtained from the parasternal long-axis view. Precise location of the straddling MV at its site of insertion is important, as this dictates whether a biventricular or single ventricle pathway is followed (41).

Figure 45.13. This set of images shows the use of the MPR mode for imaging the thin chords in a straddling MV. The lower right hand image shows the component of the MV, which inserts into the right ventricle (black arrow). The lower right hand image is the reconstructed 3-D view that shows the straddling component of the MV as well. FO, foramen ovale; IVS, interventricular septum; LA, left atrium; LV, left ventricle; PV, pulmonary valve; RV, right ventricle.

HEMODYNAMIC ASSESSMENT OF THE MITRAL VALVE

In the current era, echocardiography provides most of the hemodynamic information that is necessary to make a clinical decision with regard to intervention and its timing. Many MV abnormalities have a combination of stenosis and regurgitation. This impacts on mean gradient evaluation, which is also dependent on cardiac output. Despite this, it is an invaluable measurement in pediatric patients, whereas pressure halftime is difficult to interpret due to the higher heart rates of children compared to adults (42). The advantage of pressure halftime (Fig. 45.14A) is that it is not dependent on cardiac output, but will be affected by moderate or severe aortic regurgitation that causes the MV to close prematurely (43). It is also possible to obtain an estimation of MV area by planimetry from 3-D echocardiography (Fig. 45.14B), with this being shown to be of value in adult patients (44). As well, tricuspid or pulmonary regurgitation jets can be used to assess right ventricular and pulmonary artery pressure, which is often increased due to left atrial hypertension.

ASSESSMENT OF MITRAL VALVE REGURGITATION

Vena Contracta Size

We have already discussed the role of 3-D echocardiography in the evaluation of both the site and severity of MV regurgitation. Certainly, this technique provides superior data with regard to the site of regurgitation and can be incorporated into surgical decision making. The advantage is that the valve can be seen as a whole, and commissural and central regurgitant jets pinpointed (Fig. 45.4A). In adult patients, there appears to be a good correlation with effective regurgitant orifice area (EROA) measured by 2-D color Doppler techniques in those with circular orifices, with a weaker relationship when the jets are eccentric (45,46). This is understandable as 2-D color techniques presume that the jets are circular in shape. Of interest, for the tricuspid valve, although there is a good correlation between vena contracta width by 2-D echocardiography and vena contracta area by 3-D echocardiography, only the latter has been shown to be predictive of outcome using multivariate analysis (47). Despite this, it is still not widely utilized and clinical utility needs to be established in large adult series where it can be related to outcome and volumetric

Figure 45.14. A: The upper Doppler trace is from an adolescent with a slower heart rate so that the pressure halftime could be used to calculate MV area (1.22 cm^2). The lower trace shows the right ventricular pressure from tricuspid valve regurgitation. RVP, right ventricular pressure. B: This is from the same case as Figure 45.14A and shows MV area calculation from 3-D echocardiography using the MPR mode. Note that the planimetered area of the MV is 1.4 cm^2 , which is similar to the pressure halftime calculation. The lower right hand panel shows the true MV orifice as seen from the left atrium with 3-D echocardiography. AO, aorta; LA, left atrium; LV, left ventricle; MVA, mitral valve area; MVO, mitral valve orifice.

measurements of regurgitation. Therefore, we still have to rely on other methods, as outlined below.

Left Atrial and Left Ventricular Size

These are good indicators of the severity of regurgitation, and indeed, left ventricular end-systolic dimension is considered when determining optimal timing for surgical intervention in those with primary MV disease (48). This is not the case in

patients with associated left-to-right shunt lesions such as a ventricular septal defect or patent arterial duct, which affect not only chamber size but also flow dynamics through the MV. The main lesion that might be confused with primary MV regurgitation in the young population is regurgitation associated with anomalous left coronary artery, which results in subendocardial ischemia and papillary muscle dysfunction. In that setting, the papillary muscles are invariably sclerotic, and abnormal flow from associated coronary collaterals also can be identified (Fig. 45.15).

Figure 45.15. These images are from a child with anomalous left coronary artery from the pulmonary artery with sclerotic papillary muscles resulting in MV regurgitation. The image on the left shows the sclerotic anterior papillary muscle, indicated by the black arrow. The image on the right shows the MV regurgitation. LA, left atrium; LV, left ventricle.

Figure 45.16. This Doppler profile is from a child with significant MV regurgitation in the presence of normal left ventricular function. Note the flow reversal in the pulmonary vein profile during ventricular systole.

Pulmonary Venous Doppler Pattern

Systolic flow reversal can be seen in cases with significant regurgitation; however, it is important that more than one pulmonary vein is sampled, as a jet may be directed into one particular pulmonary vein (49) (Fig. 45.16). Limitations to this approach relate to the presence of diastolic dysfunction with raised left atrial pressure and blunted systolic forward flow.

Continuous Doppler Regurgitant Jet Profile

The more severe the regurgitation, the denser the continuous-wave Doppler profile (Fig. 45.14A). This must be taken in context as increased gain settings can enhance a Doppler signal.

Mitral E Velocity Dominance

A dominant pulsed Doppler E profile is seen in those with severe MV regurgitation. Once again, this will be affected by those cases with associated diastolic dysfunction (Fig. 45.17).

Figure 45.17. This figure demonstrates the E wave dominance of mitral inflow Doppler in a case with significant mitral valve regurgitation and no associated stenosis.

QUANTITATIVE ASSESSMENT OF MITRAL REGURGITATION BY DOPPLER

Pulsed Doppler Assessment of Regurgitant Fraction, Volume, and Effective Regurgitant Orifice Area

This technique measures the stroke volume (SV) through the mitral valve (MV) and aorta, the difference of which represents the volume of regurgitation: $SV = CSA \times VTI = \pi d^2/4 \times VTI = 0.785d^2 \times VTI$ (CSA = cross-sectional area, SV = stroke volume, VTI = velocity time integral). Regurgitant volume (mL) = $SV_{MV} - SV_{LVOT}$. Regurgitant fraction = $(SV_{MR} - SV_{LVOT})/SV_{MV}$. These are techniques that are widely utilized in adult populations and indeed play an important role in decision making (50). Limitations relate to CSA measurements in children, because any errors are squared. Similar measurements can be made by calculating the left ventricular SV by biplane Simpson's rule and subtracting the left ventricular outflow SV determined by Doppler; however, reproducibility of the SV measurements is the main problem.

Proximal Isovelocity Surface Area or Flow Convergence

Proximal isovelocity surface area (PISA) is based on the principle that as blood approaches an orifice, it forms a series of concentric, roughly hemispheric shells that increase in velocity, but decrease in area. In practical terms, the color Doppler Nyquist limit is set to a value at which aliasing occurs near the regurgitant orifice. From this the regurgitant flow is calculated as: $2\pi r^2 \times V_a$ where r = radius of aliasing velocity, V_a = velocity at which aliasing occurs. From this EROA can be calculated as: Regurgitant flow/peak velocity of regurgitation. Limitations of this technique are related to the shape of the PISA shell which may not be semicircular, multiple jets, and the effect of adjacent boundaries as well as determining the precise location of the regurgitant orifice (51). Compared to real-time 3-D echocardiography the PISA technique underestimates the true volume in comparison to the actual volume (46).

MITRAL VALVE PROLAPSE

In the pediatric population MV prolapse is infrequently encountered in patients who do not have connective tissue disorders such as Marfan syndrome. Prior to the understanding of the 3-D aspects of the mitral annulus with its two

high and two low points, the diagnosis of MV prolapse was overestimated by M-mode and in part by 2-D echocardiography (8). It was finally resolved that if the parasternal long-axis view was used then this could be used to make the diagnosis, because this view images the mitral annulus at its two

high points (Fig. 45.18). On the other hand, the apical four-chamber view should not be used, because it images the valve at the two low points (52). Using such criteria, a report from the Framington study demonstrated an incidence of 2.4% in an adult population (53).

Figure 45.18. A: This parasternal long-axis view demonstrates the 2-D features of mitral valve prolapse, with part of the anterior leaflet being behind the high point of the mitral annulus (black arrow). LA, left atrium; LV, left ventricle. B: This 3-D image of mitral valve prolapse was taken using transesophageal echocardiography. It is the same case as Figure 45.18A and shows the detail that is possible by this technique. The prolapsing segments of the valve can be seen, with the right hand panel showing the sites of regurgitation. The image with the color Doppler assessment also shows the division of the valve into segments A1-A3 and P1-P3. The mitral valve is viewed from the left atrium. AL, aortic leaflet; AO, aorta; ML, mural leaflet. C: These two images show the mitral valve from above and below, demonstrating the individual scallops of the leaflets, as well as their dysplastic nature and the commissures. AO, aorta; A1, A3, and P1-P3 represent the individual segments of the aortic and mural leaflets and is the nomenclature that is used to describe them for surgical management. D: This series of images is obtained from a MPR format and represents the reconstructed 3-D image as seen in the lower right hand panel, with the 2-D images in the upper two panels, with each being at right angles to each other. The lower left hand panel is a reconstructed image that shows how the relationship of the annulus to the prolapsing segments can be calculated using QLab software. AO, aorta; LA, left atrium; LV, left ventricle; ML, mural leaflet; PM, papillary muscle.

The posterior or mural leaflet is involved more frequently in hearts with MV prolapse and may affect a single scallop or the entire leaflet. Annular dilation depends on the presence and severity of associated MV regurgitation. Histologically, there is obvious myxomatous proliferation of the spongy layer of the leaflet. The spongiosa layer is increased with an increase in glycosaminoglycans. In this setting, myxomatous valves show disorganization in their collagen content and elastin fibers (54–56). Their chordae show an increase in glycosaminoglycans, in particular, chondroitin dermatan 6 sulphate and hyaluronan, which have the ability to bind more water, resulting in the gelatinous appearance of the leaflets and their supporting chordae.

MV prolapse that is not syndromal may well be autosomal dominant with variable penetrance. It appears that there is a linkage of myxomatous MV prolapse to chromosome 16 (MMVP1) in cases with an autosomal dominant form, while in others, there is a linkage to MMVP2 on chromosome 11p15.4 and 13q31.3-q32.1 (57,58). It may turn out that MV prolapse is similar to hypertrophic cardiomyopathy with multiple genetic abnormalities responsible for a common phenotype (4).

ECHOCARDIOGRAPHIC ASSESSMENT OF MITRAL VALVE PROLAPSE

Three-dimensional echocardiography is currently the reference standard for this entity, as it provides instantaneous recognition of not only the diagnosis but also the components of the leaflet involved (59–61). In the past, this role belonged to 2-D transthoracic and transesophageal echocardiography; however, these provided a series of snap-shot views of the MV, rather than an overall picture (at 20 degrees, scallops A3-P1 are seen; at 60 degrees scallops P3-A2-P1; at 90 degrees, scallops P3-A1; at 120–160 degrees scallops A2-P2 are seen) (62).

In the pediatric population, transthoracic 3-D echocardiography is usually adequate; however, as patients move into their teenage and young adult years, transesophageal echocardiography is superior. The transesophageal approach is helpful as with the zoom mode a real-time evaluation is possible, which overcomes the problem with stitch artifacts seen from multiple slices (Fig. 45.18B,C). The disadvantage is that the frame rate is lower, but as the MV is in the near field, the resolution is usually adequate. Importantly, it permits a precise identification of the component(s) that are prolapsing, as well as the relationship to the site and degree of regurgitation (Fig. 45.18B). More recently, with the advent of newer analysis packages it is possible to quantify the degree of MV prolapse and relate it to annular height, coaptation, and annular and leaflet area (Fig. 45.18D). This can be performed pre- and postoperatively, providing objective data regarding the quality of the surgical repair and the relationship to any persistent MV regurgitation.

It is possible to obtain multiple views of the MV leaflets and the annulus from a single four-chamber data set. This provides optimal resolution as the leaflets are imaged in the axial plane. In other cases, if the four-chamber view is inadequate, a full-volume data set can be acquired from the parasternal long-axis view; however, this images the leaflets in a lateral plane, which provides lower image resolution.

CLINICAL PRESENTATION

The clinical presentation of MV disease in children is highly variable and is influenced not only by the degree of stenosis and/or regurgitation but also by the presence and severity of

associated lesions when present. At one end of the spectrum are asymptomatic infants or children who have a heart murmur detected on routine examination. At the other end of the spectrum are infants who present early in life with poor feeding, growth failure, tachypnea, diaphoresis with feeds, and recurrent respiratory tract infections. Cardiogenic shock is typically a consequence of associated lesions such as coarctation of the aorta rather than due to intrinsic abnormalities of the MV.

Physical findings of MS include a middiastolic murmur and a late diastolic murmur during atrial systole. These murmurs are low pitched and better appreciated with the bell rather than the diaphragm of the stethoscope. They are often quiet and therefore easily missed unless there is a high clinical suspicion of MV disease. Unlike adults with rheumatic mitral stenosis S1 invariably is not increased in intensity. The pulmonary component of the second heart sound may be loud if there is pulmonary hypertension. Determining the contribution of a stenotic MV to clinical symptoms is difficult in the presence of an associated left-to-right shunting ventricular septal defect or patent ductus arteriosus, which by its very nature increases the flow across the valve if the atrial septum is intact. If an associated diastolic murmur is louder than expected for the size of the associated defect, then suspect associated MV stenosis.

Mitral regurgitation results in a high-pitched pansystolic S1-coincident murmur that may make it difficult to appreciate the first and second heart sounds. This murmur is best appreciated at the left lower sternal border and apex and may radiate to the left axilla and back. The murmur of MR may be associated with a third heart sound or even a flow rumble due to increased diastolic inflow into the LV. Hepatomegaly and increased work of breathing are other physical findings that may be present in children with either MS or regurgitation.

MV prolapse is characterized by the presence of one or more midsystolic clicks. These are believed to be caused by sudden tensing of the mitral apparatus as the leaflets prolapse into the left atrium during systole. Clicks may be followed by a high-pitched late systolic murmur of mitral regurgitation, heard best at the left lower sternal border or apex. Rarely this murmur may be “honking” in quality. The timing of the click(s) and subsequent murmur of MR depends on left ventricular loading. For example, standing results in decreased left ventricular preload, resulting in prolapse that occurs earlier in systole with a click(s) that are close to S1. However, squatting increases preload and delays the prolapse, resulting in the click moving closer to S2. Decreased left ventricular contractility or increased afterload will also delay the click. Note that not all patients with MV prolapse (MVP) have these classic auscultatory findings.

Electrocardiography

The electrocardiogram (ECG) in children with isolated MV disease may be normal if the hemodynamic consequence of the stenosis and/or regurgitation is mild. In children with moderate or severe lesions, the ECG is not diagnostic but may be an early clue to the presence of MV disease on the basis of left atrial enlargement (LAE). Criteria for LAE include a broad, biphasic P wave in one or more of leads I, II aVF, V5, and V6 and in V1 a terminal component of the P wave that is at least 40 ms in duration and at least 1 mm below the baseline (Fig. 45.19). There may also be evidence of right ventricular hypertrophy, right axis deviation, and right atrial enlargement if pulmonary hypertension is a complicating feature.

Radiography

Chest radiography is not sufficiently sensitive for the detection of heart disease in children and should not be routinely performed as part of the initial investigation of children with

Figure 45.19. Electrocardiographic findings in a 12-year-old with MS. Note the broad, notched P waves (in leads II and V1), the P wave below the baseline (V1), and the prominence of right ventricular forces (V1) consistent with pulmonary hypertension.

possible heart disease. Even among children with MV disease confirmed by echocardiography, chest radiography is not routinely necessary, as the findings often do not influence clinical management. However, chest radiography is reasonable prior to surgical or catheter interventions. Findings among patients with MS or regurgitation include straightening of the left heart border, splaying of the carina, and pulmonary venous congestion.

Magnetic Resonance Imaging

Although MRI has a valuable role in the evaluation of some CHD lesions, MV morphology is better evaluated by echocardiography than MRI due to superior spatial resolution. However, MRI may contribute to hemodynamic assessment in some patients. For example, MRI is an accurate and robust technique for measuring mitral regurgitant volume, done by subtracting aortic flow volume from left ventricular SV. Further, ventricular volumes as measured by MRI show a stronger correlation with regurgitant volumes than echocardiography-derived linear dimensions (63). Although the 2008 American Heart Association/American College of Cardiology guidelines for management of valvular heart disease in adults only describe left ventricular size in terms of linear dimensions, MRI-derived ventricular volumes (indexed to body surface area in children) may be of increasing value to guide the timing of surgical intervention. MRI can also determine anatomic regurgitant orifice area using planimetry, which in adults correlates well with MRI-derived regurgitant fraction and with catheterization and echocardiographic assessment of regurgitation severity (64).

Hemodynamic Evaluation

Diagnostic cardiac catheterization is not routinely indicated in children with MV disease, even among those with severe lesions undergoing surgical intervention, because echocardiography as an imaging modality of the MV is superior to angiography and the correlation between mean transmitral pressure gradients obtained by Doppler echocardiography and catheterization is acceptable (42). However, hemodynamic assessment may be valuable in children with mitral disease associated with other lesions. For example, in a symptomatic child with LAE, MS, and a ventricular septal defect, catheterization to calculate Qp:Qs may clarify the relative contribution

toward left atrial hypertension of the MS versus the volume load of the left-to-right shunt.

Findings at catheterization of a child with pure MS include the following. Oximetry may show mild desaturation in the setting of pulmonary edema or may indicate the presence of a left-to-right shunt (e.g., through a patent foramen ovale) in the setting of severe obstruction. Hemodynamic assessment may show pulmonary hypertension, elevated pulmonary capillary wedge pressures, and left atrial hypertension with elevated “A” waves. One exception is with supra-annular prosthetic stenosis, where the “V” wave is larger than the “A” wave and the left ventricular end-diastolic pressure is often elevated (65). Simultaneous pulmonary capillary wedge pressures and left ventricular pressures will demonstrate diastolic pressure gradients between the two. Angiography is associated with significant risk in patients with pulmonary hypertension and should be avoided unless balloon valvuloplasty is planned.

Catheterization of a child with mitral regurgitation, even severe regurgitation, is not routinely indicated prior to surgical intervention but may be helpful in patients with pulmonary hypertension or mixed obstruction and regurgitation. Findings will include elevated left ventricular end diastolic pressure, elevated left atrial pressure with large “V” waves, and increased pulmonary capillary wedge pressure. Angiography will show left atrial opacification that varies from minimal (grade I) in mild MR to complete opacification of the left atrium including the pulmonary veins with delayed emptying (grade IV) in severe mitral regurgitation. However, angiography poses the risk of a pulmonary hypertensive crisis in children with pre-existing pulmonary hypertension and therefore warrants great caution.

MANAGEMENT AND PROGNOSIS OF CONGENITAL MITRAL VALVE STENOSIS

Management of patients with congenital MS is influenced by the severity and mechanism of the obstruction and the presence of associated lesions, if any. Patients with mild or moderate stenosis typically do not warrant surgical or catheter intervention but may benefit from diuretic therapy. Patients with severe stenosis require relief of the obstruction. Interventions for relief of MS include balloon mitral valvuloplasty by cardiac catheterization, surgical mitral valvuloplasty, or MV replacement (MVR).

Medical Management

All patients with congenital MS require regular and lifelong cardiology follow-up to monitor for progression of the mitral inflow gradient, for reassessment of MR and other associated lesions, and for monitoring of possible secondary complications. Secondary complications include failure to thrive, increasing right ventricular and pulmonary artery pressures, atrial fibrillation, respiratory infections, and endocarditis. Children <2 years of age should be considered for monthly prophylaxis against respiratory syncytial virus (RSV) infection with palivizumab (66) during times of the year when community RSV infection is prevalent. Influenza vaccine should be given annually. Endocarditis prophylaxis is not required unless the patient has a prosthetic valve (67) but good dental hygiene and regular dental follow-up are important.

Balloon versus Surgical Management

McElhinney et al. (68) recently reviewed their experience of 108 children with severe congenital MS at Children’s Hospital

in Boston who underwent intervention between 1985 and 2003. The initial MV intervention was balloon valvuloplasty in 64 (59%), and was typically done in children with typical MS, double-orifice MV, or parachute MV. Balloon dilation resulted in a decrease in peak and mean transmitral gradients by a median of 33% and 38%, respectively. However, significant MR developed as a complication of this procedure in 28% of the subjects. Surgical mitral valvuloplasty was the initial intervention in 33 (31%) and these patients were more likely to have a supralvalvar mitral ring as the anatomic substrate of their MS or significant MR at baseline; the majority also underwent surgical intervention for other indications such as ventricular septal defect closure. Initial MVR was performed in 11 (10%), with the decision between surgical mitral valvuloplasty and MVR based on intraoperative assessment of the reparability of the MV. MVR was performed in an additional 24 patients after primary balloon valvuloplasty ($n = 18$) or surgical valvuloplasty ($n = 6$). Approximately, three-fourths of subjects had the prosthesis placed in the supra-annular position. Due to significant baseline differences between patients in each of these three initial treatment groups, conclusions cannot be drawn about the relative outcome benefit of one treatment strategy over another.

The surgical management of obstructive MV disease is challenging. The heterogeneous nature of congenital MS, the presence of associated lesions, and rarity of this clinical problem are likely contributing factors. Surgical, rather than balloon intervention is appropriate when the predominant mechanism of obstruction is a supralvalvar mitral ring, when there are associated lesions that warrant surgical intervention (e.g., subaortic stenosis, coarctation of the aorta) or when significant MR is also present. Surgery may be in the form of chordal fenestration when fusion is an issue, resection of subannular accessory tissue, or splitting of a solitary papillary muscle.

Recent retrospective cohorts published by large centers show that surgical intervention results in a 60% to 70% reduction in transmitral Doppler gradients and can be achieved with in-hospital mortality of 10% or less (68,69). However, moderate or severe mitral insufficiency remains a postoperative challenge. Repeat surgical mitral valvuloplasty or MVR as a follow-up procedure is necessary in 10% to 25% (68,69). Supramitral rings in the absence of other anomalies of the MV have an excellent prognosis, with only 10% having significant postoperative MR and rarely needing reintervention (68,70). One of the problems with surgical intervention in the infant is that failure to relieve the stenosis is associated with increased morbidity and less than ideal options. These children often have associated pulmonary hypertension, which makes them a poor candidate for transplantation, and MVR is challenging due to the small annular size. Therefore, it is preferable to identify those cases with significant MV stenosis early on in life when other options are more likely to result in a successful outcome. If recognized in the neonatal period, a Norwood/Hybrid approach can be undertaken, thus abandoning the left side of the heart. Also, cardiac transplantation is more likely to lead to success prior to developing sustained changes in the pulmonary vascular bed.

Mitral Valve Replacement

MVR should be avoided as initial intervention for congenital MS where possible. In young children, MVR is limited by the lack of small prostheses and the need for supra-annular implantation in some patients. However, supra-annular placement impairs left atrial compliance and results in pulmonary hypertension, even in the absence of significant prosthetic obstruction (65). The limited lifespan of prostheses, particularly bioprostheses, requiring repeated reinterventions later in

life (71,72), is an additional drawback. The Pediatric Cardiac Care Consortium reported on 102 survivors of mechanical MVR in children <5 years of age, of whom 29 (28%) underwent a second MVR a mean of 4.8 years later (72). The most common indication for second MVR was prosthetic valve stenosis (83%). Highest-risk patients for second MVR were those who were <2 years of age with prosthesis <20 mm at first MVR (72). The need for anticoagulation with warfarin for mechanical prostheses is also a major challenge, particularly in young children. Finally, operative mortality, while improving, remains a significant issue, particularly in young children (71,73). In a 30-year review of 118 children undergoing MVR at 5 years of age or less, factors associated with worse survival included MVR at <1 year of age, earlier need for redo MVR, and additional procedures at the time of MVR (74). Supra-annular placement was associated with a reduced likelihood of needing subsequent pacemaker placement, but in the latter half of the cohort (1991 to 2006) it was associated with worse survival (74).

Patient-prosthesis mismatch is also a significant consideration with respect to MVR in children. Eble et al. (75) found that compared to nonsurvivors of MVR, survivors had placement of a prosthetic valve within one z-score of the echocardiographically measured mitral annulus, while those with an oversized prosthesis had more adverse outcomes. Caldaroni et al. (76) similarly reported that an increased ratio of prosthetic valve size to patient weight was an independent predictor of death among children undergoing MVR before 5 years of age. Alsoufi et al. (77) also found that greater prosthesis size to body surface area-predicted mitral annulus ratio was an independent risk factor for death following MVR. Prostheses that are too large may contribute to left ventricular outflow tract obstruction, impaired prosthetic valve mobility, and conduction system injury. These data suggest that attempts to oversize prostheses in the hope of delaying second MVR are of little to no benefit. MVR may be particularly problematic in patients with a hypoplastic mitral annulus in which case an annular-enlarging operation may be necessary.

The use of tissue prostheses in children is limited by lack of availability of small sizes, limiting their use in young children, and also by more rapid degeneration compared to mechanical prostheses resulting in a very high rate of reoperation (78). However, unlike mechanical prostheses, tissue prostheses do not require anticoagulation with warfarin and therefore may be a good option in female adolescents and in those who are unlikely to be compliant with oral anticoagulation. Pregnancy appears safe with a tissue bioprosthesis and the low rate of valve-related complications and good functional class of this patient population is such that bioprosthesis remains a good option in some patients. Homografts have rarely been used in the mitral position and are associated with a higher reoperation risk when compared to other bioprostheses.

In summary, the management of severe congenital MS is challenging, and is associated with high reintervention rates and significant mortality. However, among children with mild to moderate MV obstruction, the prognosis is much better. In a recent review by Tierney et al. (79) of all comers diagnosed with MS before 6 months of age and managed with a biventricular strategy, independent predictors of MV intervention (catheter or surgery) or death were higher initial mean mitral inflow gradient and lower left ventricular diastolic length Z-score. Among those with an initial mean mitral gradient of <2 mm Hg, none had an intervention or died, whereas among those with an initial mean mitral gradient of >5.5 mm Hg, 85% had MV intervention or died. MV morphology was not predictive of outcome, though this study excluded those with a supramitral ring (79). Among patients with a parachute MV or a parachute-like asymmetric MV, approximately 60% maintain a biventricular circulation, but >90% require

catheter or surgical intervention, predominantly for associated lesions (80), and of those with a biventricular circulation, only about half have MS at follow-up and one-third have MR at follow-up (80). Need for intervention among children with a parachute MV is rare (37,80).

MANAGEMENT AND PROGNOSIS OF CONGENITAL MITRAL REGURGITATION

As with congenital MS, infants and children with congenital MR should be managed “medically” delaying surgical MV intervention beyond the first year of life if possible in order to avoid the complications of MVR that are associated with small patient size, should MV repair not be feasible. However, elimination of any large left-to-right shunts may be of benefit early on, should left ventricular and mitral annular dilation be contributing to the severity of MR (81). Medical management includes optimizing caloric intake and weight gain, monitoring for the possible development of pulmonary hypertension and atrial arrhythmias, aggressive management of respiratory infections, influenza vaccinations, and prophylaxis against respiratory syncytial virus infection with palivizumab for children <2 years of age. Afterload reduction and use of diuretics may be of value, though data in children are limited.

Surgical Management

The goal of surgical management of congenital MR should be to restore normal valve function rather than normal valve anatomy (81,82). Mitral reconstruction for MR has been described by Carpentier et al. (83). Stellin and colleagues recently described 48 children undergoing MV surgery for mitral regurgitation, of whom only 2 were infants, reflecting the potential to delay surgery beyond the first year of life in many cases. Surgical techniques used were cleft closure (this study excluded atrioventricular septal defects), annuloplasty, chordal shortening, commissuroplasty, and accessory orifice closure. Freedom from reintervention was 80% at 10 years, and survival was approximately 95% at 15 years and approximately 85% at 20 years. These excellent results demonstrate the feasibility of a conservative surgical approach (i.e., MV repair rather than replacement) in carefully selected patients, avoiding the complications of MVR as discussed above. Furthermore, delay of surgery in children with significant MR until the onset of severe symptoms is not associated with late left ventricular dysfunction (84), supporting the practice of delaying any surgical intervention as long as possible.

MANAGEMENT AND PROGNOSIS OF MITRAL VALVE PROLAPSE

Surgical management of MVP may be appropriate in patients with severe MR, for example, in those with a flail mitral leaflet due to rupture or severe elongation of chordae tendineae. Surgical repair of MVP is associated with excellent outcomes and is recommended over MVR, though it should be performed in centers experienced in MV repair (85). Anterior leaflet repair is associated with a higher risk of reoperation than posterior leaflet repair. Factors to consider when contemplating surgical intervention include not only the severity of the regurgitation but also left ventricular systolic function (usually normal in children and adolescents with MVP), left ventricular end-systolic and end-diastolic volumes, pulmonary artery pressure,

symptoms if any, and presence or absence of atrial fibrillation, though atrial fibrillation is unusual in the pediatric age range. Well-accepted indications for MV surgery in adolescents with MVP are the same as for those with other causes of MR, and include (a) the symptomatic patient with severe MR and NYHA class III or IV symptoms or (b) the asymptomatic adolescent with severe MR and left ventricular systolic dysfunction (ejection fraction <0.60) (48). In the unusual situation of a symptomatic patient with MR and severe LV dysfunction, cardiac transplantation may be preferable to either MV repair or replacement.

Medical management of MVP primarily involves reassurance, as most patients with MVP have mild disease and no intervention is needed. Regular exercise is recommended for most subjects. Restriction from competitive sports is prudent for those with moderate or severe left ventricular enlargement and those with aortic root dilation. The presence of a connective tissue disorder such as Marfan syndrome or Ehlers-Danlos syndrome should be considered in all patients with MVP. Metabolic and storage disorders may also be associated with MVP. Asymptomatic patients with no significant MR can be seen infrequently (every 2 to 5 years), whereas those with moderate-severe MR, symptoms, or associated aortic root dilation should be seen more often. The potential for familial inheritance of MVP should be explained, and echocardiography of first-degree family members should be considered.

Prevention of embolic complications is also a responsibility of the cardiologist. Fortunately, these are very rare in children but may infrequently be observed in adolescents. Aspirin therapy (75 to 325 mg/day) is recommended in those with MVP who experience transient cerebral ischemic attacks or who have atrial fibrillation. Warfarin therapy is recommended in those with MVP who have a history of stroke (48) in the setting of mitral regurgitation, atrial fibrillation, or left atrial thrombus (Class I indications), in which case the international normalized ratio should be kept between 2.0 and 3.0.

INTRODUCTION

The clinical spectrum of congenital aortic stenosis ranges from a nonstenotic bicuspid aortic valve to severe aortic stenosis in fetal life leading to hypoplastic left heart syndrome. Congenital aortic stenosis occurs in different forms, usually classified with respect to the location of the obstruction relative to the aortic valve: valvular, subvalvular, or supra-valvular. Because the clinical features and treatment of these forms of aortic stenosis differ, they are discussed separately in this chapter. Although this chapter deals primarily with congenital aortic stenosis and not hypoplastic left heart syndrome, the infant with severe aortic stenosis and small left ventricle presents important therapeutic issues that justify separate discussion (see Chapter 48).

VALVULAR AORTIC STENOSIS

Prevalence and Etiology

The true incidence of congenital aortic valve abnormalities is not precisely known because minor malformations of the aortic valve (primarily bicuspid aortic valves) are common, and these abnormalities clinically are frequently unapparent during infancy and childhood. Autopsy studies have reported that congenital bicuspid aortic valve occurs in approximately 1.3% of the population (1,2), and therefore is one of the most common congenital heart malformations. Given that the overall prevalence of congenital heart disease in infants is approximately 0.8% (3–5), with aortic stenosis accounting for 3% to 8% of these lesions (5–7), it is clear that minor malformations of the aortic valve are frequently undetected early in life. Only 2% of patients with congenitally abnormal aortic valve will develop significant stenosis or regurgitation by adolescence (8). Although such valves usually function well during early life, a high percentage will develop progressive valve dysfunction (stenosis and/or regurgitation) over time (9,10) and may require surgical intervention during adult life (11,12).

About 60% to 75% of cases of congenital aortic stenosis are valvular aortic stenosis (13,14). Males are affected more frequently than females, with a ratio reported to be in the range of 3:1 to 5:1 (14,15). Associated congenital heart defects occur in approximately 20% of patients with congenital aortic stenosis (16). The most common associated lesions are ventricular septal defect (VSD), coarctation of the aorta, and patent ductus arteriosus.

There is compelling evidence for an important genetic component in the etiology of aortic stenosis (17,18). Valvular aortic stenosis is known to occur in human genetic syndromes such as Turner syndrome (19) and Jacobsen syndrome (20). Non-syndromic aortic stenosis occurs sporadically or in familial

patterns compatible with autosomal dominant or multifactorial inheritance (20–22). Affected individuals within the same family can have a spectrum of cardiovascular malformations ranging from isolated bicuspid aortic valve to hypoplastic left heart syndrome. This observation not only suggests that at least some cases are caused by single-gene defects, but also that the anomalies in the spectrum of left ventricular outflow tract obstruction lesions are developmentally related. A study of first-degree relatives of 38 patients with hypoplastic left heart demonstrated that 19% had congenital cardiovascular malformations, 72% of which were left heart obstructive lesions (23). Because the recurrence risk in offspring appears to be less if the father is affected than if the mother is affected, a role for cytoplasmic inheritance of congenital aortic stenosis has been suggested as well (24).

Autosomal dominant transmission of *NOTCH-1* gene mutations has been shown to be associated with bicuspid aortic valve in some families (25). *NOTCH* genes encode transmembrane receptor proteins that are important regulators of cellular differentiation, proliferation, and specification. Genetic linkage analyses have identified several chromosomal loci associated with bicuspid aortic valve and other left ventricular outflow obstructions within pedigrees (26). Specific genes at these loci that are responsible for aortic valve development are yet to be identified. It is likely that multiple genes at different loci are involved, coding for transcription factors, extracellular matrix proteins, and signaling pathway elements that regulate cell proliferation and apoptosis.

Mechanical factors, including abnormal fluid forces, have also been implicated in the etiology of anomalies in the spectrum of left ventricular outflow tract obstruction (27). Premature closure of the foramen ovale, with resultant diminution of fetal left heart flow volume, has been associated with hypoplastic left heart syndrome (28). Manipulation of left heart flow in chick embryos leads to various forms of left ventricular outflow tract obstruction (29). It appears, then, that congenital aortic stenosis may arise from a complex interaction of genetic factors, with influence of environmental factors as well. These factors and mechanisms are not fully elucidated to date.

Approximately one-half of patients with normally functioning but abnormal bicuspid aortic valves have significant aortic root dilation (30). Mechanical factors and genetic factors have been implicated. Even without clinical stenosis, the flow velocity distribution in the ascending aorta is asymmetrical and eccentric in patients with bicuspid aortic valve, with uneven stress distribution on the aortic wall (31). The rightward anterior aspect of the ascending aorta is typically subject to increased stress, and this area has been shown to exhibit pathologic changes in the vascular smooth muscle (32). Further evidence that abnormal flow patterns contribute to aortic root dilation is the fact that patients with fusion of the left and right valve cusps usually have normal-shaped aortic roots, whereas those with right and noncoronary cusp fusion more often have a dilated ascending aorta (33). However, aortic

Figure 46.1. Diagram of aortic valve anatomy.

dilation is not strongly correlated with the degree of valve stenosis (34), suggesting a genetic basis. Pedigree analysis of relatives of patients with bicuspid aortic valve and dilated ascending aorta demonstrated a clear genetic link (35). Interestingly, a significant number of relatives had dilated ascending aortas in the absence of bicuspid aortic valve, suggesting a common genetic etiology of these different phenotypes, but specific genes have not been identified. NOTCH-1 mutations, associated with bicuspid aortic valve in some pedigrees, do not correlate with ascending aortic aneurysms (25). Mutations in fibrillin and transforming growth factor-beta genes are associated with ascending aorta dilation and other connective tissue disease manifestations in Marfan and Loeys-Dietz syndromes (see Chapter 34). However, studies have not shown an association of these gene defects with bicuspid aortic valve (36,37).

Embryology and Pathology

The aortic valve develops from three swellings, or ridges, of subendocardial tissue that form when the aortopulmonary septum divides the bulbus cordis and truncus arteriosus into aortic and pulmonary trunks. Cavitation, or “hollowing out,” of these swellings results in transformation into thin and smooth pliable leaflets and the sinuses of Valsalva (Fig. 46.1). The normal aortic valve has three pocket-like cusps, which are approximately equal in size (Fig. 46.2). At the center of the free edge of each semilunar cusp is a fibrous nodule, the

nodule(s) of Arantius, which meet in the center when the valve closes. The valve is surrounded by a fibrous ring, to which the cusps are attached.

The normal aortic valve is composed of three layers (38). The ventricular aspect of the valve leaflets is termed the ventricularis, and is composed of radially oriented elastin fibers. The aortic surface, the fibrosa, is composed of fibroblasts and circumferentially oriented collagen fibers. Between these two layers, at the base of the leaflets, is the spongiosa, a matrix composed primarily of fibroblasts, mesenchymal cells, and mucopolysaccharides.

Stenosis of the aortic valve is due to decreased orifice size that results from cusp fusion and thickening and increased rigidity of the valve leaflets. The most common malformation is the bicuspid aortic valve (Fig. 46.3), with presence of only two cusps. Bicuspid aortic valve results from partial or complete fusion of two of the aortic valve cusps, with or without a central fibrous bridge (raphé) at the site of fusion, resulting in absence of a functional commissure between the fused cusps (1). Enormous variation exists in the morphology of individual bicuspid aortic valves (11). The relative sizes of the conjoined and nonconjoined cusps may be equal or markedly asymmetrical, and the valve orifice may be central or eccentric. Most commonly, in approximately 75% of cases, the right and left cusps are conjoined. Most of the remainder have fusion of the right and noncoronary cusps, and a small minority have fusion of the left and noncoronary cusps. A raphé can be identified in approximately 75% of bicuspid aortic valves, and the raphé can be short or long, cord-like or shallow, and solid or fenestrated.

Although the majority of congenitally malformed aortic valves are bicuspid, other morphologic abnormalities account for some cases of congenital aortic valve stenosis. A unicuspid valve may result from fusion of more than one cusp, resulting in a single slit-like opening that extends to the annulus. All three cusps may be partially fused, resulting in a small central orifice. Rarely, the aortic valve cusps are relatively normal, but hypoplasia of the annulus results in stenosis (39). Myxoid dysplasia of a tricuspid nonfused valve is another uncommon pathologic substrate for congenital aortic stenosis (40).

In addition to the primary morphologic abnormality of the valve cusps, other pathologic features play a significant role in aortic valve dysmorphology and dysfunction. These factors include myxomatous degeneration, fibrosis, inflammatory changes, lipid accumulation, calcification, annular dilatation, and “acquired” fibrotic fusion of true commissures (41).

Figure 46.2. Normal aortic valve, as viewed from above. Left panel: Closed. Right panel: Open.

Figure 46.3. Stenotic bicuspid aortic valve. Note fusion of the small right coronary cusp (R) and left coronary cusp (L), with thickened and dysplastic-appearing raphe. N, noncoronary cusp.

These changes progress gradually over time, resulting in cusp thickening, stiffening, and progressive stenosis. Calcification is a rare finding in childhood and adolescence, but is almost universal in older adults with aortic valve stenosis. Calcific aortic stenosis is the third leading cause of adult heart disease (38). Progression of calcification, fibrosis, and degree of stenosis is more rapid in valves with unequal cusp sizes (11) and those with fusion of the right and noncoronary cusps (42). These progressive changes in the valve tissue are in part modulated by mechanical forces (43) and inflammatory processes (44). The mechanical stresses on the leaflets of a nonstenotic, clinically “normal,” bicuspid aortic valve are abnormal due to excessive folding and creasing, extended areas of leaflet contact, significant “morphologic” stenosis, and asymmetrical flow patterns with turbulence (31). Calcification of valve leaflets results from differentiation of mesenchymal cells into bone progenitor cells (45), but the triggers and mechanism of this osteogenic process are not fully elucidated. Increased biomechanical stress has been shown to initiate osteoblastic activity in cultured human aortic valve interstitial cells (46), and may be a major factor in the development of aortic valve calcification. Research is ongoing to delineate the molecular mechanisms that link mechanical stretch and shear stress to fibrosis and calcification of aortic valve leaflet tissue (47).

In some patients with congenitally abnormal aortic valve, cystic medial necrosis leads to an inherently weaker ascending aorta compared to normal (2,3). The media is also thinner than in normal aortas. Patients with congenital aortic valve malformation, therefore, may develop annular dilation as well as dilation or aneurysm of the ascending aorta, with risk of dissection or rupture. These findings are independent of the degree of aortic stenosis (34), but aortic regurgitation is more frequently present in patients with annular dilation. Extracellular matrix protein changes have been demonstrated in the aortas of patients with ascending aorta dilation, but whether these changes represent cause or effect is not known. Metalloproteinase activity is increased (48), and changes in collagen, laminin, and fibronectin have been demonstrated (32,49).

Left ventricular hypertrophy and myocardial fibrosis are seen in some patients with aortic stenosis. These changes may be profound with endomyocardial fibroelastosis and papillary muscle infarction that may be present in infants with severe aortic stenosis. Myocardial fibrosis may also be present in asymptomatic children with hemodynamically moderate congenital aortic stenosis (50). These findings are probably secondary changes resulting from pressure overload, and there is evidence to suggest that they may be at least partially reversible after resolution of pressure overload (51).

Physiology

The fundamental physiologic impact of aortic stenosis is obstruction of left ventricular outflow, resulting in increased afterload. Whereas in patients with normal aortic valves the systolic pressure in the left ventricle approximates the systolic pressure in the aorta, in patients with aortic stenosis the left ventricular pressure exceeds the aortic pressure during ejection. If the stroke volume is normal, the magnitude of the pressure difference reflects the severity of the stenosis.

Despite the elevation in left ventricular peak systolic pressure, the development of wall hypertrophy results in maintenance of normal wall stress, even in relatively severe aortic stenosis (52). Stroke volume, cardiac output, baseline heart rate, and ejection fraction generally remain normal, although in patients with severe symptomatic aortic stenosis, indices of contractility are decreased, and left ventricular end diastolic volume and pressure are increased.

Left ventricular subendocardial ischemia and infarction may occur in patients with valvular aortic stenosis and unobstructed coronary arteries (53). The cause of this ischemia appears to be an imbalance between coronary blood flow to the hypertrophic left ventricle and myocardial oxygen demand that increases due to pressure overload. Because intramyocardial compressive forces are greatest in the subendocardium, and this region is farthest from the epicardial coronary arteries, the subendocardium and papillary muscles are the most vulnerable myocardial regions. Patients with severe aortic stenosis and normal coronary arteries have near-maximum coronary vasodilation at rest (54). Therefore, the principal determinants of subendocardial blood flow, which occurs almost exclusively during diastole, are the length of diastole and the coronary artery driving pressure. Accordingly, the diastolic pressure time index (DPTI), which is the mean diastolic gradient between the left ventricle and aorta multiplied by the length of diastole, is an index of subendocardial blood flow (55). Mathematically, this is represented by the area between the aortic and left ventricular pressure curves during diastole (Fig. 46.4). Similarly, myocardial oxygen demand can be estimated by the systolic pressure time index (SPTI), which is the area under the left ventricular pressure curve during systole. The ratio of DPTI to SPTI has been used to quantify the oxygen supply/demand ratio of the left ventricle (56).

Although, at rest, subendocardial perfusion may be adequate to meet demand, the effects of exercise promote the development of subendocardial ischemia. Since patients with severe aortic stenosis have near-maximal coronary artery vasodilation at rest (54), there is little coronary reserve during stress. Heart rate is a critical factor in the development of a reduction in the oxygen supply/demand ratio. Although exercise stroke volume increases minimally, increased heart rate leads to shortening of both the systolic and diastolic periods. Since the left ventricle has to eject this stroke volume over a shorter time period, the left ventricular systolic pressure increases (57), and this results in increased oxygen demand. The diastolic period shortens even more than the systolic

Figure 46.4. Simultaneous pressure tracings from the left ventricle (LV) and aorta (Ao). The systolic pressure time interval (SPTI) is the area under the LV pressure curve during systole, and is a measure of myocardial oxygen demand. The diastolic pressure time index (DPTI) is the area between the aortic pressure and the left ventricular pressure during diastole, and is a measure of myocardial perfusion.

period, resulting in decreased coronary perfusion. In addition, systemic vasodilation that occurs with exercise may result in decreased diastolic blood pressure, also impairing coronary perfusion. Therefore, the effects of exercise decrease the oxygen supply/demand ratio, leading to subendocardial ischemia and even infarction.

Clinical Features and Diagnostic Methods

Symptoms

Outside of patients with symptomatic infantile aortic stenosis (discussed below), most patients with congenital aortic valve stenosis are asymptomatic during childhood. Normal growth and development are the rule. When symptoms occur, those most commonly reported are fatigability, exertional dyspnea, angina pectoris, and syncope (16). Easy fatigability is the most commonly reported symptom. This symptom has been reported by about 15% of patients with mild aortic stenosis and 31% of patients with severe aortic stenosis (58). Interpretation of the clinical significance of this symptom therefore may be difficult. Even in severe aortic stenosis, angina or syncope is uncommon, reported to occur in <10% of patients even with peak-to-peak pressure gradients >80 mm Hg (59). However, when present, angina or syncope suggests severe stenosis and mandates prompt evaluation and treatment.

Physical Exam

Except in children with severe aortic stenosis and congestive heart failure, vital signs are normal. In mild aortic stenosis the apical impulse is usually normal, but with increasing severity of stenosis, the apical cardiac impulse becomes more forceful. The presence of a presystolic tap indicates forceful atrial

contraction and suggests elevated left ventricular end-diastolic pressure. A thrill is palpable in the suprasternal notch in as many as 85% of patients with valvular aortic stenosis. A precordial thrill is also usually present in patients with moderate or severe obstruction.

The first heart sound is usually normal. Splitting of the second heart sound may not be present in severe stenosis due to prolongation of left ventricular ejection, but in most patients even with severe stenosis the second heart sound splitting is normal. In exceptionally severe cases, there may be paradoxical splitting of the second heart sound. A fourth heart sound may be present, indicating severe stenosis with diastolic dysfunction of the left ventricle and high end-diastolic pressure. Although the presence of a third heart sound is common in children and adolescents with normal hearts, it is more frequent in aortic stenosis.

The systolic crescendo-decrescendo murmur of aortic stenosis usually follows an early systolic ejection click, which is loudest at the left lower sternal border or apex, and unlike a pulmonary valve ejection click, the timing and intensity of the click do not vary with the respiratory cycle. The presence of an ejection click and suprasternal notch thrill strongly suggest that the stenosis is valvular rather than subvalvular or supraventricular. The ejection murmur is generally loudest at the upper right sternal border, or in younger children at the upper left sternal border, and it radiates into the neck over the carotid arteries bilaterally. Increasing severity of stenosis is accompanied by a louder, harsher, and later-peaking ejection murmur. In patients with aortic regurgitation, an early diastolic decrescendo murmur may also be present.

Electrocardiography

The resting electrocardiogram usually demonstrates voltage criteria for left ventricular hypertrophy if the aortic stenosis is severe. However, even in patients with peak-to-peak gradient >80 mm Hg, the ECG may be normal in up to one-third of patients (59). In patients with aortic stenosis, ECG criteria for left ventricular hypertrophy do not correlate well with left ventricular mass computed by magnetic resonance imaging (MRI) (60). The resting ECG therefore appears to be a poor discriminator of aortic stenosis severity. The presence of left ventricular hypertrophy with ST segment depression and T-wave inversion in the left precordial leads ("strain" pattern), however, is fairly specific for severe stenosis despite the relatively poor sensitivity.

Twenty-four-hour ambulatory ECG monitoring may demonstrate ventricular dysrhythmias in asymptomatic patients, and there is evidence of a strong relationship between ventricular arrhythmia and sudden death in patients with aortic stenosis (61).

Radiology

In children with aortic stenosis, the heart size on chest radiograph is usually normal or minimally enlarged. In patients with left ventricular hypertrophy, the cardiac apex may be "rounded" in the frontal projection and there may be posterior displacement of the cardiac silhouette in the lateral projection. Left atrial enlargement, if present, strongly suggests a severe degree of stenosis. Pulmonary venous congestion and other signs of congestive heart failure may be present in patients with severe stenosis and left ventricular dysfunction. Enlargement of the ascending aorta is a common finding in older children and adolescents with valvular aortic stenosis. Cardiac MRI or computed tomography (CT) scanning accurately delineates the anatomy of the ascending aorta (Fig. 46.5). Although rarely seen in children, adults with congenital aortic valve stenosis frequently have radiographic evidence of calcification of the valve.

Figure 46.5. Computed tomography images of dilated aortic root in a patient with bicuspid (but not stenotic or regurgitant) aortic valve. The patient has had repair of coarctation of the aorta. **A:** Sagittal view. **B:** Axial view. Ao, aorta; LA, left atrium; black arrow, anterior mitral valve leaflet.

Exercise Testing

The severity of aortic stenosis has been correlated with exercise capacity, systolic blood pressure response, and significant ST segment depression during exercise testing (62–65). Unfortunately, the relatively poor sensitivity and specificity of these findings limit clinical utility. However, exercise testing is usually safe, and in many cases of moderate to severe aortic stenosis may add important and useful information to the clinical evaluation. Exercise-induced ischemic ST segment changes likely reflect subendocardial ischemia due to an imbalance in the oxygen supply/demand ratio precipitated by exercise but not evident at rest (66). Successful gradient reduction by balloon valvuloplasty results in resolution of exercise-induced ischemic ST segment changes (67). In patients felt to have borderline indications for intervention, the exercise test findings may help guide management decisions. As many as 40% of “asymptomatic” aortic

stenosis patients will develop symptoms for the first time during exercise testing (68). Exercise Doppler echocardiography may provide additional information; patients with an 18 mm Hg or greater increase in the mean Doppler gradient during exercise (compared to rest) may have higher risk of cardiac events than those who have <18 mm Hg increase (69).

Echo Doppler

Echocardiography with Doppler evaluation remains the most commonly utilized modality in defining the anatomy and assessing the severity of aortic stenosis. The normal aortic valve has three thin and mobile cusps that open and close symmetrically (Fig. 46.6). Imaging of the aortic valve in different planes allows characterization of the valve anatomy and mechanisms of dysfunction. The long-axis view of the left ventricular outflow tract demonstrates decreased

Figure 46.6. Echocardiographic parasternal short-axis views of a normal tricuspid aortic valve. **A:** Diastole. **B:** Systole. R, right coronary cusp; L, left coronary cusp; N, noncoronary cusp.

valve mobility and systolic doming of the cusps (Fig. 46.7). The aortic valve annulus dimension is best measured in the long-axis view. Imaging in the short axis demonstrates the anatomy of the valve cusps and commissures. Many bicuspid aortic valves have a raphé between the conjoined cusps, and during diastole the valve may appear tricuspid (Fig. 46.8). Careful analysis of the valve motion, however, frequently demonstrates that the valve opens and closes with the “fish mouth” appearance of a bicuspid valve. In addition to details of the aortic valve pathology, evaluation

of left ventricular mass and systolic function are performed, as well as evaluation for other associated defects including other sites of left-sided obstruction. M-mode and two-dimensional measurements are performed to quantitate left ventricular dimensions and shortening fraction. Unfortunately, direct measurement of the orifice area from two-dimensional images has not proven accurate (70,71). Three-dimensional echocardiography may provide more detailed anatomical imaging of the valve morphology and more accurate measurement of the orifice area (72).

Figure 46.8. Echocardiographic parasternal short-axis views of a bicuspid aortic valve. A: Diastole, with cusps closed and appearance of three separate cusps. B: Valve opening during systole, with fusion of the right and left coronary cusps (F) evident. R, right coronary cusp; L, left coronary cusp; N, noncoronary cusp; AS, atrial septum; LA, left atrium.

Although in most children the acoustic windows allow very good transthoracic imaging of the aortic valve, transesophageal echocardiography (TEE) is useful in patients whose transthoracic imaging is suboptimal. TEE is more sensitive than transthoracic echocardiography for evaluation of vegetations in patients with endocarditis. TEE is also helpful in the perioperative setting to evaluate valve morphology and mechanism of dysfunction prior to repair or replacement, and to evaluate the status of the valve (repaired, autograft, or prosthesis) immediately after weaning from cardiopulmonary bypass.

Color Doppler and spectral pulse and continuous wave Doppler are performed to confirm localization of the obstruction and to quantitate the degree of stenosis. Injecting a fixed stroke volume through a small valve orifice results in rapid flow velocity; this relationship is quantitated by the modified Bernoulli equation, which states that the instantaneous pressure gradient across the valve (in mm Hg) is equal to the flow velocity (m/s) squared multiplied by four (73). The peak instantaneous pressure gradient is calculated using the maximum Doppler velocity, usually obtained by continuous wave Doppler interrogation. The angle of incidence of the Doppler interrogation is important; multiple tracings should be recorded from different views (suprasternal notch, right parasternal, apical, subcostal) and the maximum velocity should be used to calculate the peak instantaneous pressure gradient.

Traditionally, the catheter-derived peak-to-peak pressure gradient has been used to estimate clinical severity of aortic valve stenosis and to guide management decisions. Because the peak pressure in the aorta occurs after the peak pressure is reached in the left ventricle, the Doppler-derived peak instantaneous pressure gradient represents a different physiologic parameter than the catheter-derived peak-to-peak pressure gradient (74) (Fig. 46.9). The peak instantaneous gradient is higher than the peak-to-peak gradient (75), and these two different measurements of pressure gradient are not

interchangeable. In addition, the peak instantaneous Doppler gradient obtained from different echocardiographic windows are not equivalent; the suprasternal notch gradient was significantly higher than the gradient obtained from the apical position in a study designed to evaluate the predictive value of Doppler-derived gradients with respect to those measured in the catheterization laboratory (76). The mean systolic pressure gradient can be calculated from the Doppler spectral profile, and this correlates fairly well with the mean pressure gradient derived from simultaneous catheter recordings (75,77). Some investigators favor using mean pressure gradient to guide clinical decision making (78).

The 2006 American College of Cardiology/American Heart Association Task Force Report Guidelines for the Management of Patients with Valvular Heart Disease (8) recommends the guidelines for grading the severity of aortic stenosis according to the Doppler-derived gradients. Mild stenosis is present when the peak instantaneous gradient is <36 mm Hg (jet velocity 3 m/s) or the mean gradient is <25 mm Hg. Moderate stenosis is present when the peak instantaneous gradient is between 36 and 64 mm Hg (jet velocity between 3 and 4 m/s) or the mean gradient is between 25 and 40 mm Hg. Severe stenosis is present when the peak gradient is >64 mm Hg (jet velocity 4 m/s) or the mean gradient is >40 mm Hg. These guidelines, of course, are valid only in patients with normal ventricular function and absence of other defects, such as a VSD, which can result in a measured gradient that underestimates the true severity of the stenosis due to “pop off” of left ventricular ejection through the VSD.

All pressure gradient estimations depend not only on the severity of the obstruction, but also on underlying hemodynamic conditions, which may vary significantly at different times in the same patient. States of increased contractility or stroke volume will result in higher pressure gradients than states of decreased contractility or stroke volume, and for a given stroke volume, a faster heart rate (decreased ejection time) results in a higher pressure gradient. The same patient may have significantly different gradient measurements during general anesthesia as compared to an alert and anxious state. In addition, patients with severe obstruction may have abnormally low myocardial systolic performance and low cardiac output, resulting in low pressure gradients. For this reason, many clinicians advocate using valve area calculations rather than pressure gradient measurements to gauge the severity of obstruction and guide management decisions.

The most commonly used method to calculate aortic valve area using echocardiography with Doppler involves use of the continuity equation, which simply states that the volume of flow per cardiac cycle is the same at the aortic valve orifice as it is at the mitral valve annulus (79) or in the left ventricular outflow tract below the valve (80). Using the left ventricular outflow tract, one may calculate the aortic valve area (cm^2) by multiplying the LVOT cross-sectional area (cm^2) and the mean velocity in the LVOT (cm/s) and then dividing this by the mean velocity through the valve orifice (cm/s). In children, the aortic valve area should be indexed to body surface area. In full-grown adolescents and adults, the normal aortic valve area is 3.0 to 4.0 cm^2 . The following guidelines classify the degree of stenosis based on valve area: area >1.5 cm^2 (mild stenosis), area between 1.0 and 1.5 cm^2 (moderate stenosis), and area <1.0 cm^2 (severe stenosis). In children, the normal aortic valve area is approximately 2 cm^2/m^2 ; area <0.6 cm^2/m^2 represents severe stenosis (8).

Tissue Doppler imaging may be helpful in assessment of diastolic and systolic left ventricular myocardial dysfunction in patients with aortic stenosis. The presence of symptoms in patients with preserved ejection fraction has been attributed to diastolic dysfunction, with associated elevated filling pressures and increased myocardial stiffness (81). Traditionally,

Figure 46.9. Simultaneous left ventricular (LV) and aortic (Ao) pressure tracings demonstrating the difference between peak instantaneous pressure gradient (PIG) and peak-to-peak pressure gradient (P-P).

Figure 46.10. MRI angiogram in a patient with valvular aortic stenosis. **A:** Diastole, with closed valve. The aortic root is dilated. Ao, aorta; LV, left ventricle. **B:** Systole. Doppler parameters derived from mitral or pulmonary vein flow have been used for estimation of left ventricular filling pressure, but these measurements are dependent on loading conditions, heart rate, and other factors that limit clinical usefulness. Use of tissue Doppler imaging to measure systolic and diastolic mitral annular velocities allows quantification of systolic long-axis function and diastolic function. In patients with aortic stenosis, the ratio of early mitral inflow velocity (E) to early diastolic mitral annular velocity (E') correlates with the left ventricular end diastolic pressure (82), thereby providing a clinically useful noninvasive method of assessing diastolic dysfunction. In addition, measurement of the mitral annular systolic velocity (S') by tissue Doppler imaging may demonstrate systolic long-axis dysfunction in patients with aortic stenosis even in the presence of normal ejection fraction and normal indexes of transverse function (82). Because longitudinally oriented fibers are present in the subendocardial region, and the subendocardium is most susceptible to ischemia in patients with aortic stenosis, these fibers are at greater risk than the circumferentially oriented fibers (83). Long-axis dysfunction therefore might be expected to precede transverse axis dysfunction.

Cardiac Magnetic Resonance Imaging

Cardiac MRI (Fig. 46.10) is a useful noninvasive tool for assessment of left ventricular mass and function, and velocity-encoded MRI techniques allow quantification of pressure gradients and aortic valve area. Such measurements have been shown to correlate well with Doppler measurements of the same parameters (84). Cardiac MRI may also accurately define the anatomy of the valve morphology (Fig. 46.11), ascending aorta, annulus size, and coronary artery origins.

Cardiac Catheterization

Due to the evolution of noninvasive techniques that accurately diagnose and evaluate the anatomy and severity of aortic valve stenosis, cardiac catheterization is generally undertaken primarily for the purpose of therapeutic balloon valvuloplasty in patients with known aortic valve stenosis and noninvasive evidence of severe obstruction. However, diagnostic catheterization may still be indicated if the clinical data and noninvasive evaluation are not consistent. Information obtained from cardiac catheterization has been considered to be the “gold standard” to which traditional and emerging noninvasive modalities have been compared. Complete hemodynamic assessment in the catheterization laboratory

includes measurement of cardiac output (Fick technique and/or thermodilution), left ventricular end-diastolic pressure, and pressure gradients (mean and peak to peak). Access to the left ventricle may be either transeptal or retrograde. Angiography of the left ventricle permits evaluation of left ventricular cavity size and function, aortic valve annulus size, degree of leaflet thickening and cusp mobility, patency and origin of the coronary arteries, and the size and contour of the ascending aorta.

Hemodynamic measurements can be used to calculate the effective valve orifice area by the method of Gorlin (85). The aortic valve area is calculated by dividing the aortic valve flow (AVF) by the product of 44.3 and the square root of the mean pressure gradient across the valve.

$$\text{Aortic valve area (cm}^2\text{)} = \frac{\text{AVF}}{44.3 \sqrt{\text{mean pressure gradient}}}$$

The AVF, which occurs during systole, is determined from the cardiac output and systolic ejection period (SEP). The systolic ejection time (SET) for a single cardiac cycle is measured

Figure 46.11. MRI image of bicuspid aortic valve. Although a raphe is not visualized, there is fusion of the right and left coronary cusps (R+L). N, noncoronary cusp; AS, atrial septum. (Courtesy of E.S. Rivera and T. Geva.)

Figure 46.12. Pressure tracings from the aorta (Ao) and left ventricle (LV) used for calculation of the aortic valve area using the Gorlin equation. The systolic ejection time (SET) is the time period during which there is flow through the valve orifice into the aorta, and this occurs during the period of time when the left ventricular pressure is greater than the aortic pressure. The shaded area (ΔP) represents the pressure gradient, from which the mean pressure gradient during systole can be calculated using planimetry.

from simultaneous pressure tracings from the aorta and left ventricle (Fig. 46.12), which by multiplying by the heart rate gives the SEP per minute (s/min).

$$\text{SEP (s/min)} = \text{SET (s/beat)} \times \text{HR (beats/min)}$$

The AVF (mL/s) is then determined by dividing the cardiac output (mL/min) by the SEP (s/min).

$$\text{AVF (mL/s)} = \frac{\text{Cardiac output (mL/min)}}{\text{SEP (s/min)}}$$

The mean pressure gradient (mm Hg) is determined by planimetry using simultaneous pressure tracings from the aorta and left ventricle. The aortic valve area (cm^2), then, is calculated by taking the square root of the mean pressure gradient and multiplying this by 44.3, then dividing this into the AVF. In theory, the aortic valve orifice area represents the most reliable index of stenosis severity, more reliable than other parameters (such as pressure gradients) that are dependent on loading conditions and heart rate. Unfortunately, the calculation of the valve area may not always accurately reflect the degree of obstruction seen clinically. Measurements used in calculation of aortic valve area must be made with extreme care and precision, and the calculated aortic valve area should be considered along with the entire body of clinical data when formulating management decisions.

Natural History

The natural history of aortic stenosis is not completely known, due largely to the fact that techniques for diagnosing and quantitating aortic stenosis have developed simultaneously with the evolution of surgical and transcatheter treatment modalities. The 1993 Report from the Second Joint Study on the Natural History of Congenital Heart Defects (NHS-2) represents the study with the largest number of patients and longest follow-up period. However, this report still only provides complete data on 235 patients (51% of the original NHS-1 cohort) with median follow-up of 22.5 years (range 17 to 29 years; ages 17 to 49 years) (86). In addition, congenital aortic valve disease encompasses a wide spectrum from critical infantile aortic stenosis to normal functioning bicuspid aortic valve. Only about 1 in 50 of the 1.3% of the population with congenitally bicuspid aortic valves will develop significant valve dysfunction by adolescence (8).

Despite the lack of very long-term intervention-free data, natural history studies have provided important information. Patients who present in infancy with aortic valve stenosis generally have more severe stenosis and higher mortality with or without treatment (87–89). Twenty-five of the patients in the original NHS-1 cohort (90) were <2 years old; the 1-year survival rate was 64%, and most had undergone surgical intervention. In contrast, the 25-year survival in patients who were 2 years of age or greater at the time of original enrollment was 85%. An older study by Campbell (14), published in 1968, found that the mean age of death in patients with aortic stenosis was 35 years, with 40% mortality by age 30 and 60% mortality by age 40. Over half of the patients who died had sudden unexpected death, whereas most of the remaining deaths were due to progressive congestive heart failure. The notion that sudden death is extremely rare in the absence of preceding symptoms has been challenged by several recent studies including NHS-2 (86,91,92). About half of sudden death cases from aortic stenosis occur during or immediately after exercise (93). In the current era, children with aortic stenosis treated by balloon valvuloplasty have an extremely low risk of sudden unexpected death (94).

Although mild aortic stenosis may remain mild for many years (86), progression over time is the rule (14,91,95–97). The rate of progression is highly variable in individual patients. The rate of progression may be greater in children than in adolescents and adults due to inability of the valve orifice to increase in proportion to somatic growth (98). Outcome is highly correlated with the initial gradient, with those having higher gradients at the time of diagnosis developing symptoms, dying, or requiring valve replacement sooner than those with lower gradients (86,91). In addition to the progression of aortic stenosis, many patients will develop significant and progressive aortic valve regurgitation over time, particularly if they have had surgical valvotomy or percutaneous balloon valvuloplasty (86). Patients with fusion of the right and noncoronary cusps are at risk of more rapid progression of valve dysfunction (99).

Risk of bacterial endocarditis has been reported to be as high as 1% per year (14), but the risk is probably less based on the data from NHS-2, where the incidence rate was 27.1 cases per 10,000 person-years (100) (0.27% per year). Although bacterial endocarditis risk is present even in patients with bicuspid aortic valve without stenosis, the incidence of endocarditis is higher in patients with more severe stenosis.

Treatment

Medical Treatment and Balloon Valvuloplasty

Because progression of valve dysfunction is the rule, medical management is essentially expectant, with timing of intervention being the primary focus. There are currently no medical

therapies known to alter the progression of aortic valve dysfunction. Because adult aortic stenosis is a progressive process that resembles atherosclerosis, the effect of lipid-lowering medical therapy with statins has been studied, but has not been shown to be helpful in curbing the progression of aortic valve changes (101). In contrast to older adults with aortic stenosis, for whom intervention is recommended only when symptoms develop or are considered imminent (8,102), indication for intervention in children and adolescents is more liberal. Whereas for older adults 20-year survival is considered long-term, in children and adolescents the goal is survival for many decades. In asymptomatic patients with severe congenital aortic stenosis, relief of the obstruction likely reduces the risk of sudden cardiac death and decreases the extent of subtle and progressive myocardial injury and interstitial myocardial fibrosis (91,92,103,104).

Although surgical valvotomy may still be performed, balloon valvuloplasty (105) has generally supplanted open surgical valvotomy as initial treatment for congenital aortic valve stenosis in infants, children, and adolescents. Both procedures are generally safe and effective in relieving the obstruction (106), but in either case, subsequent progression of stenosis and/or valve regurgitation is anticipated (88,107–112), with valve replacement considered to be the eventual definitive treatment. Nevertheless, balloon aortic valvuloplasty in many cases postpones the need for surgery by several years, even decades (111,112). A retrospective study of late outcomes after balloon aortic valvuloplasty in children (109) showed a freedom from reintervention rate of 46% at 12 years. In infants and children, delaying the need for valve replacement can allow for growth, permitting insertion of a larger replacement valve when valve replacement becomes necessary. Predictors of less favorable outcome and need for early reintervention or surgery include small aortic annulus, depressed left ventricular function, and mitral valve dysfunction (110).

Adults with congenital aortic valve stenosis generally have developed valve calcification, diminishing the chances of good results from either surgical valvotomy or balloon valvuloplasty, and therefore valve replacement is the primary treatment beyond young adulthood. In older patients with severe aortic stenosis who are not surgical candidates, balloon valvuloplasty is associated with poor survival (113), but has been shown to be a successful bridge to transcatheter aortic valve implantation (114). Children and adolescents with aortic stenosis who have significant aortic valve regurgitation (either native disease or after previous valvotomy or balloon valvuloplasty) also require valve replacement therapy (or surgical repair) rather than valvotomy or balloon valvuloplasty.

The American Heart Association 2011 Scientific Statement on Indications for Cardiac Catheterization and Intervention in Pediatric Cardiac Disease (115) provides guidelines for the management of infants and children with congenital aortic valve stenosis. Given the absence of clinical trial data, these recommendations are based on nonrandomized studies and expert opinion rather than data from randomized prospective clinical trials. For infants with isolated critical ductal-dependent valvular aortic stenosis, or any infant or child with isolated aortic stenosis with left ventricular systolic dysfunction, balloon valvuloplasty is indicated regardless of the measured pressure gradient. Most infants and children with aortic stenosis are asymptomatic, however, and the guidelines recommend that the catheter gradient should be measured. If the catheter-measured peak-to-peak gradient is ≥ 50 mm Hg, then balloon valvuloplasty is indicated. If the patient desires to play competitive sports, become pregnant, has ischemic or repolarization changes on rest or exercise ECG, or has symptoms of angina or syncope, then balloon valvuloplasty is justified if the peak-to-peak gradient is ≥ 40 mm Hg. Other causes of the symptoms or ECG changes should be sought if the gradient is

<40 mm Hg. Valvuloplasty is not recommended for asymptomatic patients with peak-to-peak gradient <40 mm Hg unless cardiac output is impaired, in which case, the gradient underestimates the true severity of the obstruction.

These guidelines are intended for patients under conscious sedation. For patients under deep sedation or general anesthesia, the measured gradients are likely to be lower, and the guidelines state that it is reasonable to consider balloon valvuloplasty in asymptomatic patients if the mean Doppler gradient when not sedated is >50 mm Hg, even if the measured catheterization-derived peak-to-peak gradient is <50 mm Hg. However, given the relatively slow rate of progression of stenosis outside of infancy (86), caution should be exercised in borderline cases due to the risk of introducing significant aortic regurgitation that might progress and necessitate valve replacement sooner than might have occurred without intervention.

For patients with milder degrees of aortic stenosis, periodic follow-up with interval medical history, physical examination, 12-lead ECG, and echo Doppler study is recommended (8). According to the American College of Cardiology/American Heart Association 2006 Guidelines for the Management of Valvular Heart Disease (8), for adolescents and young adults with peak Doppler gradients <50 mm Hg or mean gradients <30 mm Hg, follow-up is recommended every 2 years. For those with peak Doppler gradients >50 mm Hg or mean gradients >30 mm Hg, follow-up should be yearly. These guidelines seem reasonable for most children as well, although infants and young children should be followed more closely as progression of aortic valve dysfunction may be more rapid. Exercise ECG testing should be considered for patients who are interested in athletic participation. If the clinical findings and the echo-Doppler evaluation are disparate, then cardiac catheterization may be indicated for complete hemodynamic assessment including direct measurement of the peak-to-peak gradient.

The 36th Bethesda Conference Task Force recommendations for competitive athletics (116) defines patients to have mild aortic stenosis if the catheter-derived peak-to-peak gradient is <30 mm Hg, the mean Doppler gradient is <25 mm Hg, or the peak instantaneous Doppler gradient is <40 mm Hg. Such patients are permitted to participate in all competitive sports if they are asymptomatic and have normal exercise tolerance. Asymptomatic patients with moderate aortic stenosis (peak-to-peak gradient 30 to 50 mm Hg, mean Doppler gradient 25 to 40 mm Hg, or peak Doppler gradient 40 to 70 mm Hg) may participate in sports with a low static component and low-to-moderate dynamic component (such as golf, bowling, baseball/softball, and volleyball) so long as they have only mild or absent left ventricular hypertrophy, absence of repolarization abnormality on ECG, and a normal exercise test. In addition, if such patients also have no history of supraventricular tachycardia or ventricular tachyarrhythmia at rest or with exercise, then they may participate in sports with moderate static component and low dynamic component (such as diving, archery, equestrian, and motorcycling). Patients with severe aortic stenosis (peak-to-peak gradient >50 mm Hg, mean Doppler gradient >40 mm Hg, or peak Doppler gradient >70 mm Hg) should not participate in any competitive sports. For aortic valve stenosis patients who also have significant aortic regurgitation, these recommendations must be considered in concert with the Task Force recommendations for aortic regurgitation.

Even in the absence of stenosis or significant regurgitation, patients with bicuspid aortic valve are at risk of progressive aortic root dilation and aortic dissection; the mortality risk is as high in younger patients as in those over 40 years old (117). The risk of aortic dissection is nine times greater in patients with a bicuspid aortic valve compared to those with

a tricuspid aortic valve (10). Because of the high prevalence of bicuspid aortic valve, it is a more common etiology of aortic dissection than Marfan syndrome (118). In children, dilation is usually mild and aortic complications are rare (119). However, approximately half of young adults with a bicuspid aortic valve have significant aortic root dilation (30). Most patients with aortic dissection have hypertension (120,121), and this helps to explain the strong association of aortic dissection with bicuspid aortic valve and aortic coarctation (10). Aggressive and meticulous management of hypertension is therefore the mainstay of medical treatment. Although the benefit of prophylactic β -blocker or angiotensin converting enzyme (ACE) inhibitor therapy has not been proven in normotensive patients with aortic root dilation associated with congenitally abnormal aortic valve, such treatment is reasonable for those patients who tolerate β -blockers or ACE inhibitors. The angiotensin receptor blocker losartan is an antihypertensive medication that also inhibits transforming growth factor- β signaling, and is now frequently used in this setting. Increased transforming growth factor- β signaling has been implicated as an important factor in aortic root dilation in Marfan syndrome, Loeys-Dietz syndrome, and some patients with familial thoracic aneurysm and dissection (122), but this mechanism has not been demonstrated in patients with bicuspid aortic valve-associated aortic dilation. Nevertheless, the potential association in some patients may justify the use of losartan as the antihypertensive medication of choice in this setting. Because aortic root dilation is a precursor of aortic dissection, careful surveillance with serial noninvasive imaging examinations is warranted to detect progressive aortic root dilation so that prophylactic surgery can be performed preemptively before aortic dissection occurs. Prophylactic surgery is sometimes recommended in asymptomatic adolescents or young adults if the aortic diameter reaches 4.5 cm (or 2.5 cm/m²) in diameter (123), or if the rate of growth of the aorta is rapid and out of proportion to somatic growth (124).

Pregnancy can be managed conservatively in women with mild aortic stenosis and normal left ventricular function (8). In women with moderate to severe aortic stenosis, pregnancy should be deferred until the stenosis is successfully treated by valvuloplasty or valve replacement. Women with moderate to severe aortic stenosis who become pregnant should be followed closely. If symptoms develop or left ventricular dysfunction develops, consideration should be given to either balloon valvuloplasty or surgery (8). If significant aortic root dilation is present, there is risk of aortic dissection, particularly in the third trimester, and the aortic root size should be followed closely along with careful attention to blood pressure control.

Infective endocarditis prophylaxis precautions are no longer recommended for patients with congenital aortic valve stenosis (125). However, those with prosthetic valves or surgically repaired valves with prosthetic material remain candidates for premedication with antibiotics in the event of a procedure expected to induce bacteremia.

Aortic Valve Surgery

Aortic valve replacement is usually required in patients who develop progressive aortic valve regurgitation or recurrent stenosis refractory to balloon valvuloplasty. Surgical repair of the aortic valve (126) may be possible in some cases, although generally such repairs are considered palliative, as with balloon valvuloplasty, with eventual expectation of valve replacement. Replacement with a mechanical prosthesis currently provides the most durable result, but the patient must be anticoagulated and there is no growth potential, both of which are very significant problems in small children. Use of bioprosthetic valves, either homograft or heterograft, prevents the need for anticoagulation, but growth potential is still a major issue, and

the longevity of these valves is frequently poor, particularly in small children. In some centers, the Ross procedure (127) is the preferred procedure, particularly in infants and small children. In this procedure, the patient's pulmonary valve is translocated to the aortic position, and a pulmonary homograft is implanted in the pulmonary valve position. The need for anticoagulation is avoided, and importantly the autograft (neo-aortic valve) has growth potential. The major disadvantage of the Ross procedure is that pulmonary homograft dysfunction is universal, frequently relatively early in children. Given current technology, children who undergo a Ross procedure can expect several additional procedures over their lifetime for recurrent pulmonary homograft dysfunction. In addition, progressive neo-aortic valve dysfunction, with or without dilation of the neo-aortic root, is not uncommon over time. However, modifications of the Ross operation have reduced the incidence of these complications, and in many cases, the function of the autograft valve remains excellent for many years (128–130).

Percutaneous aortic valve implantation is a promising new technique that has been developed as an alternative to surgical valve replacement in adult patients with severe aortic stenosis who are deemed inoperable (131). Currently, this procedure is not an option for children and adolescents with congenital aortic stenosis, but results in inoperable elderly patients and in patients with high surgical risk have shown significant improvement in survival compared to medical treatment (132) and similar rates of survival at 1 year compared to surgical replacement (133). As advances are made in device materials and design, and implantation techniques are refined, transcatheter aortic valve replacement may be a viable option for children and adolescents in the future.

Long-Term Outcome

Congenital aortic valve disease is a lifetime disease. Although interventional and surgical techniques have resulted in marked improvement in the prognosis of this disease, there is no currently available medical, interventional, or surgical approach that renders the aortic valve normal. Given the relatively high incidence of congenitally abnormal aortic valve and the likelihood of eventually developing clinically important complications, this condition may be responsible for more deaths and morbidity than all other forms of congenital heart disease combined (10,134). Lifelong follow-up of these patients is mandatory. As new valve replacement technologies and techniques evolve, continued improvement in outcomes should follow.

VALVULAR AORTIC STENOSIS IN INFANCY

Clinical Features

Although the majority of patients with congenital aortic valve stenosis are asymptomatic in childhood, approximately 10% present during infancy with symptoms and signs of congestive heart failure (89). Improvements in fetal imaging and diagnosis have led to prenatal diagnosis of severe aortic valve stenosis in many cases (135). Anatomically, the valve may be bicuspid or unicuspid, with thickening and myxoid dysplasia. In some patients, there may be no identifiable cusps or commissures.

In utero, the presence of mild or moderate aortic stenosis results in increased left ventricular pressure and possibly left ventricular hypertrophy, which may be well tolerated. With more severe stenosis, the left ventricular hypertrophy is more severe, and the resultant decrease in left ventricular compliance may lead to decreased flow through the left heart and ultimately in hypoplasia of the left ventricle, mitral valve, aortic

valve annulus, and left ventricular outflow tract. Coarctation of the aorta may also be present, with or without hypoplasia of the ascending aorta. Endomyocardial fibroelastosis and/or papillary muscle infarction may occur due to oxygen supply/demand mismatch, and severe fetal aortic stenosis may evolve into hypoplastic left heart syndrome (136). The fetus usually tolerates severe aortic stenosis, even in cases of severe left ventricular hypoplasia, since the right ventricle is capable of handling the entire cardiac output. Once the fetus is born and separated from the placental circulation, however, symptoms may develop rapidly.

If the left ventricular size and function are adequate to handle the entire cardiac output, symptoms and signs may be mild or absent even after closure of the ductus arteriosus. However, poor feeding, tachypnea, and growth failure may occur. A systolic murmur is usually present, and gallop rhythm may be noted. Hepatomegaly may be present, and peripheral pulses may be weak.

In more severe cases of neonatal aortic stenosis, the left heart may not have the capacity to handle the entire cardiac output and closure of the ductus arteriosus may result in circulatory collapse. Such infants are pale and poorly perfused, with poor pulses, hepatomegaly, tachycardia, gallop rhythm, hyperdynamic right ventricular impulse, tachypnea with retractions, and usually (but not always) a systolic heart murmur (88). Such infants may appear well prior to closure of the ductus arteriosus, which may not occur for several days after birth. Careful attention to the neonatal physical exam findings, such as hyperdynamic right ventricular impulse and differential cyanosis, is necessary to avoid presentation in extreme cardiovascular collapse after discharge from the hospital. Routine neonatal screening with upper and lower extremity pulse oximetry has been recommended by some for early detection of ductal-dependent left heart obstructive lesions.

Evaluation and Management

Echocardiography with Doppler evaluation confirms the diagnosis and delineates the details of the anatomy in infants with critical aortic stenosis. The aortic valve is frequently thickened with reduced mobility and a small orifice. The left ventricle is usually hypertrophic with relatively small cavity size, but it may be dilated and poorly contractile. Abnormally increased echogenicity of the endomyocardium and/or mitral valve papillary muscles may be present (Fig. 46.13), representing endomyocardial fibroelastosis and/or papillary muscle infarction. The right ventricle is frequently enlarged. Careful assessment of the size and function of the left ventricle and mitral valve is imperative, as is evaluation for other left-sided obstructions such as aortic coarctation, cor triatriatum, supraannular mitral stenosis, and pulmonary vein stenosis. The ascending aorta may be hypoplastic or dilated.

Doppler interrogation of flow in the proximal ascending aorta demonstrates increased velocity and turbulence. The calculated gradient, however, may underestimate the severity of the stenosis if left ventricular function is depressed, a significant portion of the systemic cardiac output is provided by the right ventricle via the patent ductus arteriosus, and/or there is significant left ventricular ejection ("pop off") through a VSD. The status of the ductus arteriosus and the direction and magnitude of ductal flow is an essential part of the evaluation, including the direction of flow in the distal aortic arch.

Initial management of neonatal critical aortic stenosis consists of maintaining ductal patency with prostaglandin E₁ infusion, inotropic support if the left ventricular function is impaired, and avoidance of supplemental oxygen if the systemic circulation is ductal dependent. If mechanical ventilation is necessary, hyperventilation should be avoided.

Figure 46.13. Echocardiographic parasternal long-axis image in an infant with critical aortic stenosis demonstrating severe endomyocardial fibroelastosis (double arrows) and infarcted papillary muscle (P). LA, left atrium; LV, left ventricle; Ao, aorta.

In neonates with critical aortic stenosis and small left ventricle, more definitive management involves a decision regarding adequacy of the left heart to support a two-ventricle circulation. Several studies have addressed methods of quantitatively assessing the adequacy of the left heart to handle the entire systemic circulation. Infants with non-apex-forming left ventricle, small aortic annulus (<5 mm), and small mitral valve annulus (<9 mm) may have improved survival with Norwood-type palliation or cardiac transplant than with treatment strategies to achieve a two-ventricle circulation (137). Rhodes et al. (138) developed a predictive equation for success of two-ventricle management plan in neonates with isolated critical aortic stenosis. The parameters that were most predictive of success or failure included aortic root dimension indexed to body surface area, the ratio of the long axis of the left ventricle to the long axis of the heart, and the indexed mitral valve area. In a prospective multicenter analysis performed by the Congenital Heart Surgeons Society (139), a regression equation was used to predict 5-year survival probability with Norwood-type palliation versus two-ventricle approach. Discriminating parameters included age, z-score of aortic valve, grade of endomyocardial fibroelastosis, diameter of ascending aorta, presence of significant tricuspid valve regurgitation, and z-score of left ventricular length. Significant retrograde flow in the distal aortic arch via the patent ductus arteriosus is also associated with lower likelihood of success with a two-ventricle approach (140). Cardiac MRI may provide more accurate quantification of left ventricular size, morphology, and function than echocardiography, and therefore might improve decision making regarding the choice of treatment approach (141).

For infants with severe or critical isolated aortic valve stenosis deemed to have adequate left heart structures for two-ventricle circulation, initial therapy usually entails balloon valvuloplasty or surgical valvotomy (open or transventricular). Although some advocate open surgical valvotomy as the treatment of choice for critical neonatal aortic stenosis (142), studies have demonstrated similar outcomes with the less invasive percutaneous

balloon valvuloplasty procedure (143,144), which in most centers is the preferred procedure in the majority of cases. It appears that open surgical valvotomy may result in higher likelihood of residual or recurrent stenosis, whereas balloon valvuloplasty may be associated with a higher incidence of important aortic regurgitation (145). Techniques for balloon aortic valvuloplasty include antegrade approach via the foramen ovale from venous access, as well as retrograde approach via femoral, umbilical, or carotid artery access (146). As with children and adolescents, balloon valvuloplasty is considered palliative. In a retrospective review of 113 neonates who underwent balloon aortic valvuloplasty, the reintervention-free survival was 48% at 5 years (147). The goal is to postpone the need for surgery, which likely is inevitable in the vast majority of patients.

Given the issue of growth, as well as the poor durability of tissue valves in the aortic position in infants, aortic valve replacement with mechanical or bioprosthetic valves is an undesirable option in neonates and infants with congenital aortic stenosis. The Ross procedure (pulmonary autograft), with Konno-type enlargement of the aortic annulus, may offer a durable aortic valve with growth potential and is thus a viable option as primary therapy for severe aortic stenosis in infants (148). Resection of endomyocardial fibroelastosis may increase growth potential of the borderline left ventricle. Although the results of this technique have not been systematically compared with surgical valvotomy or balloon valvuloplasty, anecdotal success has been reported (149). Another surgical approach in neonates with critical aortic stenosis and borderline left ventricle is to perform a stage I Norwood operation with subsequent reoperation to achieve a two-ventricle repair (150). More recently, temporary palliation has been accomplished by the stage I hybrid procedure (bilateral pulmonary artery band placement and stenting of the ductus arteriosus) (151). Determination of left ventricular adequacy may be more reliable after this period of temporary palliation, and successful outcome may be enhanced when definitive surgery is postponed to outside of the neonatal period.

Balloon dilation of aortic stenosis in the unborn fetus may prevent or reverse left heart hypoplasia in the fetus (135). Early attempts resulted in limited success with high mortality, but more recent advancements in patient selection and techniques offer the prospect that fetal intervention may one day have a role in the management of critical congenital aortic stenosis and possible prevention of hypoplastic left heart syndrome.

SUBVALVULAR AORTIC STENOSIS

Prevalence and Etiology

Fixed subvalvular aortic stenosis accounts for approximately 10% to 20% of cases of aortic stenosis in children, and the male to female ratio is 2:1 to 3:1 (152,153). Associated cardiac defects are present in more than half of cases (152,154). Common associated defects include VSD, coarctation of the aorta, atrioventricular septal defect, and valvular aortic stenosis. Mitral valve anomalies are also frequently present, and likely play a role in the pathophysiology of the obstruction in some patients (155,156).

Except for cases of malalignment VSD with posterior deviation of the outlet septum into the left ventricular outflow tract, subvalvular aortic stenosis is rare in infants. Most cases seem sporadic, although familial subaortic stenosis has been reported (157,158). Although most cases appear to develop postnatally, there may be a genetic substrate in many cases, and interestingly, this genetic substrate appears to not be specific for subaortic stenosis but rather also includes lesions of right ventricular outflow tract obstruction (159).

Despite the evidence for genetic etiology in some cases (160), the fact that discrete fixed subaortic stenosis is rarely seen in the fetal or neonatal heart has led many investigators to regard it as an acquired rather than a congenital lesion (161–165). The development and subsequent progression of fixed subaortic stenosis in children without previous evidence of left ventricular outflow tract obstruction supports this notion (166). It is likely that fixed subaortic stenosis develops due to an abnormal endothelial substrate that undergoes abnormal proliferation due to some stimulus. One such stimulus might be abnormal shear stresses caused by abnormal flow patterns that result from variations in geometric and anatomical features of the left ventricular outflow tract (167,168), such as increased mitral–aortic separation (161) and steeper aortoseptal angle (169–171). The tissue substrate for development of subaortic stenosis remains uncertain, although maldevelopment or persistence of embryonal endocardial cushion tissue has been hypothesized (153,172).

Pathology

The obstruction in fixed subvalvular aortic stenosis usually consists of a collar or ridge of membranous and/or fibromuscular tissue encircling the left ventricular outflow tract, or in some cases it may be diffuse and tunnel-like (152,173). The membranous curtain may arise from a thicker, muscular base. Histology of the fibrous tissue demonstrates dense collagen fibers, elastic fibers, and myocytes (174). Fibrous tissue may be closely related or “tethered” to the aortic valve or to the anterior mitral leaflet (165). Mitral valve anomalies are common, and these include insertion of a papillary muscle or chordal tissue into the septum or aortic leaflet, accessory mitral valve tissue, and “muscularization” of the subaortic portion of the anterior leaflet (155). The aortic valve may be thickened, and is usually tricuspid. The aortic valve abnormality appears to be acquired, and may be a consequence of the turbulent flow jet damaging the aortic valve cusps (175–178), but might also result from progression of the underlying disease substrate.

Physiology

The physiology of fixed subaortic stenosis is similar to valvular aortic stenosis, with pressure overload of the left ventricle resulting in hypertrophy. In most cases, the amount of hypertrophy correlates with the degree of obstruction, but in some cases, it may be out of proportion to the degree of obstruction (179). As with valvular aortic stenosis, in severe cases, subendocardial oxygen demand may exceed supply and result in subendocardial ischemia and fibrosis.

Clinical Features and Diagnostic Method

The diagnosis of subaortic stenosis frequently surfaces during echocardiographic evaluation at the time of diagnosis or follow-up of associated congenital heart disease, such as VSD or coarctation of the aorta. Patients with isolated subaortic stenosis usually present with an asymptomatic heart murmur. Commonly, the patient initially is thought to have an innocent murmur, and as the stenosis progresses, the murmur becomes more typical of pathologic left ventricular outflow tract obstruction. As in the case of valvular aortic stenosis, chest pain and syncope may occur, but generally only when the stenosis is severe.

The systolic ejection murmur is loudest at the mid left sternal border, and radiates to the upper sternal borders and into

the suprasternal notch. A systolic click is rare, and this helps to differentiate subvalvular aortic stenosis from valvular aortic stenosis. The left ventricular impulse may be hyperdynamic, and the associated findings of aortic regurgitation and/or mitral valve regurgitation may be present. The ECG usually demonstrates left ventricular hypertrophy, even in many cases with mild stenosis (179), although the ECG may occasionally be normal even in severe subaortic stenosis (152,153). Chest radiograph is generally normal, and dilation of the ascending aorta is much less common than in valvular aortic stenosis (153,154).

Echocardiography with Doppler evaluation is highly sensitive and specific for making the diagnosis of subaortic stenosis and to define the anatomy of the lesion (180,181). Early systolic partial closure and "fluttering" of the aortic leaflets may be present (182). Careful evaluation of the aortic and mitral valve anatomy and function is mandatory, as is a thorough search for other associated lesions. Pulsed Doppler demonstrates velocity acceleration and aliasing in the outflow tract beneath the valve, and continuous wave Doppler allows accurate calculation of the peak instantaneous and mean pressure gradients (183). Coexistent valvular aortic stenosis is confirmed by an additional velocity increase above the aortic valve by pulsed Doppler. TEE may be helpful in further defining the anatomy of the left ventricular outflow tract, and is commonly performed intraoperatively to assist in the repair by evaluating the anatomy and valve function pre- and post-operatively.

Diagnostic cardiac catheterization is not mandatory in the evaluation of subaortic stenosis, but may provide useful information in cases where the clinical data and noninvasive evaluation are not consistent. Peak-to-peak and mean pressure gradients can be determined, and left ventricular end diastolic pressure can be measured. In the case of coexistence of valvular and subvalvular aortic stenosis, slow and careful pullback across the left ventricular outflow tract using an end-hole catheter will quantitate the degree of obstruction across both sites (Fig. 46.14). Angiography in the right anterior oblique and long axial oblique views may clearly demonstrate the anatomy of the lesion, but echocardiography (particularly TEE) also reliably delineates the anatomy of subaortic stenosis (181) (Fig. 46.15–46.17).

Natural History

In infants and children with associated cardiac malformations, the natural history is influenced significantly by the coexisting disease. In general, subaortic stenosis is a progressive lesion (98,152,184) and occasionally progressive obstruction occurs rapidly (166). However, rate of progression of mild subvalvular aortic stenosis is variable, and the obstruction may remain mild and stable for many years in children and adults (185–187). Factors associated with more rapid progression of obstruction include higher initial pressure gradient, short distance between the obstructive lesion and the aortic valve, and anterior mitral valve leaflet involvement (188,189).

Aortic regurgitation is a frequent finding in subaortic stenosis, most commonly mild but occasionally moderate or severe (176,190). Doppler peak instantaneous gradient >50 mm Hg and increased age at diagnosis are risk factors for moderate or severe aortic regurgitation, but these parameters are not sensitive and prediction of development and progression of aortic regurgitation in patients with subaortic stenosis is difficult (178). Aortic regurgitation is common in adults with unoperated subaortic stenosis, but is rarely hemodynamically significant (186). Children at low risk for aortic valve dysfunction are those with mild gradient, thin, and mobile aortic valve leaflets, and subaortic lesion not in close proximity to the aortic valve (178).

Treatment

Although balloon dilation has been reported, long-term success is limited, and treatment for subaortic stenosis is surgical. The indications for surgery are not universally agreed upon. Because obstruction can be rapidly progressive, and because aortic regurgitation may be the result of progressive damage to the aortic leaflets by turbulent flow, there is rationale for early intervention (191–193). The increased probability of aortic regurgitation at follow-up in patients with higher preoperative gradient and older age of operation supports this approach (194). However, in the era of echocardiography, patients are frequently diagnosed with very mild subvalvular aortic stenosis, and it is clear that progression of disease is highly variable.

Figure 46.14. Pressure recording from an end-hole catheter as it is pulled back slowly from the body of the left ventricle (LV body) to the aorta. The left ventricular systolic pressure immediately beneath the valve is equal to the systolic pressure in the aorta, indicating absence of valvular aortic stenosis.

Figure 46.15. Echocardiographic images of discrete membranous subaortic stenosis. A: Apical five-chamber view. B: Parasternal long-axis view. (M, subaortic membrane; LA, left atrium; LV, left ventricle; AV, aortic valve.)

Many patients with mild subaortic stenosis remain stable for many years, without progression and without aortic regurgitation (185,186). In addition, there is evidence that aortic regurgitation may develop in operated and nonoperated patients (190), and in fact may be more prominent after surgical

intervention than in nonoperated patients (186,195). It appears that children with subaortic lesions not in close proximity to the aortic valve, mild obstruction (peak Doppler gradient <30 mm Hg), and aortic valve cusps that are thin and mobile may be managed conservatively, with close follow-up to detect

Figure 46.16. Echocardiographic parasternal long-axis views of fibromuscular subaortic stenosis, with broad-based subaortic fibromuscular ridge. A: Diastole, with aortic valve closed. B: Systole, with aortic valve open.

significant progression (178,195). Patients with progressive obstruction should have surgical relief of obstruction.

Surgical management consists of resection of obstructive tissue in the left ventricular outflow tract. Muscle resection in addition to membrane excision may decrease the risk of recurrent subaortic stenosis (196), which may be as frequent as 20%. Some recurrences may be cases of inadequate relief of obstruction at the time of initial surgery (176). Surgical correction of mitral valve abnormalities that contribute to the subaortic obstruction, such as anomalous papillary muscle insertion, should also be performed to reduce the risk of residual or recurrent stenosis (155). In addition to residual obstruction, complications of surgery include heart block, worsening of aortic or mitral valve regurgitation, and inadvertent creation of a VSD. Patients with tunnel-like left ventricular outflow tract obstruction have highest risk of complications, including inadequate relief of obstruction. In some cases of severe subaortic stenosis, particularly if the aortic annulus is small, more extensive tissue resection is necessary to achieve adequate relief of obstruction, and a Konno procedure (197) or Ross/Konno procedure (148) may be utilized.

Long-Term Outcome

Many patients with isolated membranous discrete subaortic stenosis have complete and lasting surgical relief of obstruction without aortic or mitral valve dysfunction. However, many have mild aortic valve dysfunction, which may progress despite adequate relief of obstruction, and recurrence or incomplete relief of subaortic stenosis is not uncommon. Periodic long-term follow-up is prudent for all patients with subaortic stenosis. In postoperative patients, further intervention may be indicated if recurrent stenosis or aortic regurgitation progresses. In addition, patients frequently require follow-up care for other associated cardiac defects. Some feel that endocarditis prophylaxis precautions are advisable indefinitely in most patients due to aortic valve thickening and regurgitation (even if very mild) and/or residual turbulence in the left ventricular outflow tract; however, the revised AHA guidelines do not recommend prophylaxis.

SUPRAVALVULAR AORTIC STENOSIS

Prevalence and Etiology

Supravalvular aortic stenosis is the least common type of aortic stenosis. It is rare, estimated to occur in approximately 1 of 25,000 live births (198), which accounts for approximately 0.5% of congenital heart disease cases. Approximately 30% to 50% of patients with supravalvular aortic stenosis have Williams-Beuren syndrome (199,200), features of which include supravalvular aortic stenosis, peripheral pulmonary stenosis, mental retardation, and characteristic facial appearance. About 20% of cases are familial but without other features of Williams-Beuren syndrome, and the remaining cases, about half, appear to be sporadic.

The etiology of supravalvular aortic stenosis is reduced or abnormal expression of the elastin gene on chromosome 7q11.23 (201). Familial "isolated" supravalvular aortic stenosis appears to result from a discrete mutation involving the elastin gene (202,203), whereas other features of Williams-Beuren syndrome result from disruption of the elastin gene together with other neighboring genes (204). Genetic transmission is autosomal dominant, with heterozygotes expressing only 50% of the normal amount of elastin, resulting in reduced arterial elastin content and abnormal elastin fiber geometry. Sporadic cases of

supravalvular aortic stenosis appear to be from either new mutations of the elastin gene or possibly from variable expression of the autosomal dominantly transmitted mutation (205,206). Large arteries such as the aorta and proximal pulmonary arteries have high elastin content in the media, and therefore are more commonly affected than smaller arteries (207).

Pathology

Reduced elastin in the arterial media results in reduced elasticity and markedly thickened media with smooth muscle hypertrophy, disorganization, and increased collagen deposition (208). Most commonly, the stenosis is localized primarily to the sinotubular junction, but approximately one-fourth of patients have diffuse narrowing of the entire ascending aorta and in some cases the transverse aorta (209). The main and/or proximal branch pulmonary arteries are frequently stenotic (210,211), and branches of the aortic arch may be involved (212). Stenoses of the renal and mesenteric arteries may also be present in as many as 30% of patients with supravalvular aortic stenosis (210–212).

The peripheral attachment of the aortic valve commissures is at the level of the sinotubular junction, and in patients with supravalvular aortic stenosis the aortic valve cusps may be thickened and adherent to the narrowed sinotubular junction (213,214). Abnormalities of the aortic valve may be present in as many as half of patients with supravalvular aortic stenosis (207). Coronary blood flow may be impaired by adhesion of an aortic valve leaflet to the sinotubular junction, or by thickening of the aortic wall, especially if the orifice is located close to the sinotubular junction (209,215). The coronary arteries may also manifest primary structural changes related to the underlying elastin arteriopathy as well as secondary hypertensive changes resulting from the fact that they originate proximal to the obstruction (216,217).

Physiology

Although the physiology of supravalvular aortic stenosis is similar to that of valvular and subvalvular aortic stenosis, the manifestations are exacerbated by the fact that the coronary arteries orifices are proximal to the obstruction. Not only does this expose the coronary arteries to high pressure during systole, with resultant secondary effects on the coronary vasculature, but also the stenosis may limit diastolic flow into the coronary arteries. Given that coronary ostial abnormalities are not uncommon as well, patients with supravalvular aortic stenosis are at significant risk of subendocardial ischemia, fibrosis, papillary muscle infarction, and sudden death due to oxygen supply/demand mismatch (56,218,219).

Clinical Features and Diagnostic Method

The majority of patients with supravalvular aortic stenosis are diagnosed during evaluation of an asymptomatic heart murmur. Published surgical series, which probably include the more severe spectrum of patients, report a high incidence of symptoms, which are present in more than half of cases (220,221). Symptoms include angina, syncope, cardiac arrest, and dyspnea on exertion.

The systolic murmur is similar to that of valvular aortic stenosis, most prominent at the upper right sternal border with radiation into the suprasternal notch and into the neck. Frequently, a suprasternal notch thrill is palpable. A systolic click is uncommon. Blood pressure in the right arm is frequently greater than that in the left arm due to the Coanda effect (222). Differences in upper extremity blood pressures

Figure 46.18. Left ventricular angiogram in a patient with elastin arteriopathy demonstrating supravalvular aortic stenosis. **A:** AP projection. **B:** Lateral projection. The diameter at the sinotubular junction (STJ) is considerably smaller than the diameter of the aortic annulus (AN), and the entire aorta (Ao) is small. Note the origin of the coronary arteries in close proximity to the sinotubular junction. (LV, left ventricle.)

and carotid artery pulses may also result from stenosis of the aortic arch branches.

Findings of associated cardiovascular anomalies are frequently present, and these include branch pulmonary artery stenosis, coarctation of the aorta, patent ductus arteriosus, mitral regurgitation, VSD, atrial septal defect, and tetralogy of Fallot (223–226). Patients with Williams-Beuren syndrome have “elfin” facies and other characteristic features. Many are musical savants.

The ECG may be normal or demonstrate left ventricular hypertrophy, T-wave abnormalities, and/or ST segment depression. These findings are not specific. The chest radiograph is usually normal. Echocardiography with Doppler is highly sensitive in making the diagnosis of supravalvular aortic stenosis, but at times does not completely delineate the anatomy of the ascending aorta, aortic arch, and aortic branches. Cardiac catheterization with angiography will define the anatomy and physiology in detail (Fig. 46.18), particularly in cases where aortic valve disease coexists, but MRI (227) and multidetector CT scanning are less invasive, lower risk methods of accurately defining the anatomy. The risk of cardiac catheterization is significant (212,220), with cardiac arrest presumably resulting from impairment of coronary flow from contrast injection and/or catheter manipulation near the coronary ostia at the site of severe supravalvular stenosis.

In addition to carefully delineating the anatomy of the supravalvular aortic stenosis, it is imperative that other sites of possible elastin vasculopathy are also thoroughly evaluated. Noninvasive imaging of the aortic arch branches, pulmonary arteries, and renal arteries is mandatory prior to embarking on surgical treatment for supravalvular aortic stenosis.

Natural History

The natural history of supravalvular aortic stenosis is not well known, in part due to the rarity of the disease and also because of the rapid evolution of diagnostic modalities and surgical techniques over the past few decades. In general, supravalvular aortic stenosis tends to progress, whereas coexistent pulmonary artery stenosis tends to improve over time (224,228). Sudden cardiac death has been reported (212,214).

Treatment

Although balloon dilation (229) and stent treatment (230) of supravalvular aortic stenosis have been reported, the close proximity to the aortic valve and coronary artery orifices are

significant obstacles and currently, surgical management is the treatment of choice. Indications for surgery are not clearly defined, but most centers use pressure gradient criteria similar to those in valvular aortic stenosis. Certainly, the presence of symptoms warrants prompt consideration for surgery. Some feel that bacterial endocarditis prophylaxis precautions are advisable, but AHA guidelines do not include this lesion.

Surgical techniques include simple patch enlargement of the sinotubular junction above the noncoronary sinus (231), extended aortoplasty with an inverted bifurcating patch into the noncoronary and right coronary sinuses (232), and Brom’s technique with insertion of separate patches in all three sinus after transecting the aorta (233). Any obstruction to coronary blood flow should be surgically corrected at the time of supravalvular aortic stenosis repair, and this may include patch enlargement of coronary ostial stenosis and/or internal mammary artery bypass grafting (234,235). If there is diffuse stenosis of the ascending and/or transverse aorta, the most common surgical technique is augmentation using an elongated patch, with the use of deep hypothermic circulatory arrest if necessary to extend the patch far enough to adequately relieve the obstruction (207).

Long-Term Outcome

Long-term outcome after surgical repair of supravalvular aortic stenosis is not known, but it appears that with current surgical techniques the rate of restenosis is very low (220,233). Because of the high likelihood of aortic valve abnormality, though usually mild, and other vascular lesions associated with elastin vasculopathy, long-term monitoring of the cardiovascular status in patients with supravalvular aortic stenosis is prudent.

Robert H. Beekman, III

In its simplest form, coarctation of the aorta is a discrete stenosis of the proximal thoracic aorta (Fig. 47.1). However, considerable variation exists in coarctation anatomy as well as in its pathophysiology, clinical presentation, treatment options, and outcomes. For example, although often a discrete stenosis, coarctation may be a long segment in nature, may be associated with hypoplasia of the transverse aortic arch (common in infancy), or may be abdominal in location. The pathophysiology of coarctation varies with the severity of the stenosis, and also is affected by the presence of associated lesions, such as patent ductus arteriosus, ventricular septal defect, or left ventricular outflow obstruction. The clinical presentation of coarctation also varies, ranging from heart failure in infancy to asymptomatic hypertension and/or a murmur in an older child or adult. Treatment options include surgery (most commonly resection and end-to-end anastomosis) and percutaneous balloon angioplasty and stenting. Finally, clinical outcomes and long-term prognosis after treatment vary widely and are not entirely benign. In many patients, the late prognosis is affected by residual coarctation stenosis or arch hypoplasia, associated intracardiac pathology, and resting or exercise hypertension. It is correct to conclude that coarctation of the aorta is not the simple lesion it often appears to be.

PREVALENCE AND ETIOLOGY

Coarctation of the aorta occurs in approximately 6% to 8% of patients with congenital heart disease. The New England Regional Infant Cardiac Program (NERICP) (1) identified coarctation of the aorta as the fourth most common lesion requiring cardiac catheterization or surgery during the first year of life. Coarctation accounted for 7.5% of infants encountered in the program between 1969 and 1974. The prevalence is actually higher because the NERICP reported only infants having intervention during the first year of life. As with most left-sided obstructive lesions, coarctation occurs more commonly in males than in females, with a male:female ratio ranging from 1.27 to 1.74 (1,2).

A genetic influence on the development of coarctation has long been recognized in patients with Turner XO syndrome, in whom about 35% are affected. More recent data suggest that there is an important genetic influence on the development of left-sided obstructive lesions (3–8). For example, linkage studies have identified multiple overlapping genetic loci for left-sided obstructive lesions, including coarctation, strongly supporting the notion that these lesions are causally related (6,7). NOTCH1 mutations have been identified in some patients with bicuspid aortic valve, aortic valve stenosis, coarctation, and hypoplastic left heart syndrome (8). Environmental influence on the development of coarctation also has been suggested by a study detecting a seasonal

variation, with the incidence of coarctation peaking in the late fall and winter (9).

PATHOLOGY

Coarctation of the aorta is typically a discrete stenosis in the upper thoracic aorta, at or near the point of the insertion of the ductus arteriosus (Fig. 47.2). Most coarctations, therefore, are properly described as juxtaductal in location. The gross morphology of coarctation includes an intimal and medial malformation and a prominent posterior infolding (the posterior shelf), which, in some cases, extends around the entire circumference of the aorta (10). In fact, the gross pathology of coarctation varies considerably. Coarctation is most often a discrete stenosis (Fig. 47.3), but may be associated with isthmus and transverse arch hypoplasia (Fig. 47.4), or may be long segment and/or tortuous. In infants, particularly those with associated left-ventricular outflow obstruction or a ventricular septal defect, there may be diffuse hypoplasia of the transverse aortic arch (Fig. 47.5) and isthmus proximal to a discrete coarctation (11,12). Less commonly, coarctation of the aorta occurs in other locations, such as the ascending aorta or the abdominal aorta. Coarctation of the abdominal aorta is a complex long-segment stenosis that typically is associated with renal artery stenosis.

Histologic examination reveals thick intimal and medial ridges that protrude posteriorly and laterally into the aortic lumen (Fig. 47.2). Associated intimal thickening and hyperplasia are particularly prominent in older patients (10). The ductus or ligamentum arteriosus inserts at the same level anteromedially. Intimal proliferation and disruption of elastic tissue may occur distal to the coarctation (the jet lesion), at a site where high-velocity flow impacts the arterial wall. It is this distal site where infective endarteritis, intimal dissections, or aneurysms may occur. Cystic medial necrosis, consisting of depletion and disarray of medial elastic tissue, occurs commonly in the aorta adjacent to the coarctation site (13) and in the ascending aorta as well. In some patients, cystic medial necrosis provides the histologic substrate for late aortic aneurysm formation or dissection.

Coarctation of the aorta may be associated with intracardiac pathology in some patients. Children who present in infancy are much more likely than older patients to have an associated ventricular septal defect and/or left ventricular outflow obstruction. Ventricular septal defects associated with coarctation include the perimembranous, muscular, or malalignment types. With a malalignment ventricular septal defect, posterior deviation of the conal septum may cause significant left ventricular outflow tract obstruction (14,15). A bicuspid aortic valve occurs in up to 85% of patients with a coarctation, and the valve may be stenotic or the annulus hypoplastic. Mitral

Figure 47.1 Aortogram demonstrating a discrete coarctation of the thoracic aorta. A somewhat tortuous left internal mammary artery is apparent.

stenosis also occurs in patients with coarctation and may be caused by a supravalvar mitral ring, thickening and dysplasia of the mitral leaflets, short dysplastic chordae tendineae, or the presence of a single “parachute” papillary muscle (16). The association of multiple left-sided obstructive lesions with

coarctation has been referred to as Shone syndrome (17), and constitutes a challenging group of lesions when treatment is required in infancy. Other intracardiac anomalies that may be associated with coarctation include atrioventricular septal defects, D-transposition with or without tricuspid atresia, the Taussig-Bing type of double-outlet right ventricle, and congenitally corrected transposition of the great arteries. Coarctation also is an important component of the hypoplastic left heart syndrome.

Extracardiac vascular anomalies are present in many patients with coarctation and include variations in brachiocephalic artery anatomy, a collateral arterial circulation, and aneurysms of the circle of Willis. Thoracic coarctation usually occurs just beyond the origin of the left subclavian artery, but variations in the brachiocephalic arterial vessels may occur. The left subclavian artery may arise at the site of coarctation and may be stenotic at its origin. The right subclavian artery arises anomalously below the coarctation as the last brachiocephalic branch in 4% to 5% of cases. Reversed vertebral artery flow to a subclavian artery arising at or below a coarctation may produce the subclavian steal syndrome. A collateral arterial circulation, augmenting perfusion to the descending aorta, may develop by childhood or adolescence but is rarely present in infancy. This collateral system has two components: an anterior and a posterior collateral circulation. The anterior circulation develops between internal mammary arteries and the external iliac arteries via the epigastric arterial system. The posterior collateral circulation develops between the thyrocervical arteries and the descending aorta via retrograde flow through enlarged intercostal arteries. These intercostal arteries may become dilated and tortuous, producing palpable thoracic thrills, continuous murmurs, and rib notching on the chest roentgenogram. Finally, saccular (“berry”) aneurysms occur in the circle of Willis in 3% to 5% of patients with coarctation. These may be responsible

Figure 47.2 Upper left: Autopsy findings in a typical juxtaductal coarctation. The posterior shelf (arrow) is seen opposite a patent ductus arteriosus (DA). Upper right: Discrete coarctation (arrow) with DA distally. Lower left: DA inserts distal to a hypoplastic transverse aortic arch. There is poststenotic dilation of the aorta distally. Lower right: Elastic stain demonstrating disorganized media and intimal proliferation on the discrete “posterior shelf” on the right, opposite the DA; P, proximal aortic lumen; D, distal aortic lumen.

for cerebral vascular accidents in some patients with arterial hypertension.

Extracardiac nonvascular anomalies are also common in patients with coarctation of the aorta. In addition to Turner XO syndrome, abnormalities of the musculoskeletal system, genitourinary system, gastrointestinal system, or respiratory

Figure 47.4 Aortogram demonstrating a very severe coarctation with hypoplasia of the aortic isthmus and transverse arch. A tiny ductus is seen entering at the site of the coarctation. A catheter is positioned in the ascending aorta via an atrial transeptal puncture.

Figure 47.5 Left ventricular angiogram (lateral projection) in an infant with coarctation of the aorta and hypoplasia of the transverse aortic arch. The transverse arch is moderately between the carotids and the left subclavian artery. There is a patent ductus arteriosus which inserts beyond the coarctation.

system are present in as many as 25% of children with coarctation (1,18). There is also an increased incidence of head and neck abnormalities in patients with coarctation, raising the possibility that a neural crest abnormality may be involved in the embryogenesis of coarctation (19).

EMBRYOLOGY

The aortic arch and its branches develop during the sixth to eighth week of human gestation. The embryologic third aortic arches persist as the common carotid arteries. The left fourth aortic arch forms the thoracic aortic arch and isthmus, and the right fourth arch normally involutes. The embryologic sixth aortic arches persist as the proximal pulmonary arteries, with the left sixth aortic arch developing distally into the ductus arteriosus. Thoracic coarctation is, therefore, a manifestation of abnormal development of the embryologic left fourth and sixth aortic arches (20). The underlying cause is not well understood. Two concepts have been advanced, neither of which is entirely satisfactory: the ductus tissue theory and the hemodynamic theory.

Coarctation occurs most commonly at the site of insertion of the ductus arteriosus. The ductus tissue theory proposes that coarctation develops as the result of migration of ductal smooth muscle cells into the periductal aorta, with subsequent constriction and narrowing of the aortic lumen (21). This concept is concordant with the clinical observations that coarctation often becomes manifest after ductus closure and that it may be palliated in the newborn with prostaglandin E_1 infusion. However, the ductal tissue theory does not adequately explain aortic coarctation that occurs distant from the insertion of the ductus arteriosus, such as in the transverse arch or abdominal aorta.

The hemodynamic theory proposes that coarctation develops because of hemodynamic disturbances that reduce the volume of blood flow through the fetal aortic arch (22). In the normal fetus, the aortic isthmus receives only 10% of the combined ventricular output, which explains the observation that

Figure 47.6 Simultaneous pressure recordings from the ascending and descending aorta in a child with coarctation, before and immediately after balloon angioplasty. Prior to angioplasty (**left panel**) typical pressure contours are demonstrated: The systolic and pulse pressures are elevated in the ascending aorta and diminished in the descending aorta. A pressure gradient is present throughout systole and diastole. After angioplasty (**right panel**), the pressure contours are normalized, with the peak systolic gradient decreasing from 50 to 5 mm Hg.

the normal isthmus diameter is only about 70% to 80% of the diameter of the neonatal ascending aorta (22). According to the hemodynamic theory, intracardiac lesions that diminish the volume of left ventricular outflow promote development of coarctation in the fetus by reducing flow through the aortic isthmus. This theory does help to explain the common association of coarctation with ventricular septal defect, aortic stenosis, and hypoplasia of the transverse aortic arch. It is also consistent with fetal echocardiographic studies demonstrating that hypoplasia of the transverse arch and isthmus are common in fetuses with coarctation (23). An interesting variation of the hemodynamic theory has been proposed to account for the occurrence of coarctation in girls with Turner syndrome. It is suggested that fetal lymphatic obstruction, which may cause the webbed neck in Turner syndrome, also leads to distended thoracic ducts that compress the fetal ascending aorta and promote the development of coarctation (24).

HEMODYNAMICS

Fetal hemodynamics are rarely disturbed by the presence of a coarctation because normally only 10% of the combined ventricular output traverses the aortic isthmus in utero. After birth, with closure of the foramen ovale and ductus arteriosus, a substantially larger volume flow must cross the stenotic aortic segment. Therefore, important hemodynamic disturbances may occur postnatally. Depending on the severity of coarctation and the presence of associated cardiac lesions, these hemodynamic changes range from mild systolic hypertension to severe heart failure and shock.

Coarctation of the aorta increases impedance to left ventricular outflow and elevates systolic pressure in the left ventricle, the ascending aorta, and its branches. Depending on the severity of the stenosis, the cardiac output, and the extent of

the collateral circulation, the systolic pressure gradient generated across a coarctation may be as high as 50 to 60 mm Hg at rest. In many patients, a pressure gradient from ascending to descending aorta exists throughout systole and diastole (Fig. 47.6). Multiple compensatory mechanisms assist the left ventricle in response to the increase in outflow impedance. Left ventricular myocardial hypertrophy is perhaps the most important. Myocardial hypertrophy tends to normalize myocardial wall stress and ventricular afterload (25) and helps maintain normal systolic ventricular function. In isolated coarctation, left ventricular end-diastolic volume is typically normal, and the end-systolic volume may be reduced. Thus, left ventricular ejection fraction is normal to increased in most children with coarctation of the aorta (in the absence of heart failure).

If a coarctation is severe or develops rapidly, as in a newborn upon ductal closure, left ventricular systolic dysfunction and heart failure may ensue. The hemodynamic consequences include diminished stroke volume, increased left ventricular end-diastolic pressure, elevated left atrial pressure, pulmonary venous congestion, and pulmonary artery hypertension. If cardiac output is severely compromised, diminished myocardial perfusion and the development of acidosis further depress myocardial contractility. This clinical scenario is particularly common in the first weeks of life. Compensatory mechanisms include activation of the sympathetic nervous system (to increase heart rate and enhance myocardial contractility) and the Frank-Starling mechanism (to increase left ventricular end-diastolic volume and help maintain a normal stroke volume). The immature myocardium, however, is relatively ineffective in using these compensatory responses (26). The neonatal myocardium lacks mature sympathetic innervation as a result, in part, of a decrease in sympathetic beta-receptor density. Further, compared with the adult myocardium, the neonatal left ventricular myocardium is poorly compliant and less able to enlist the Frank-Starling mechanism to preserve ventricular stroke volume. Finally, with severe coarctation in

the newborn, left ventricular pressure overload occurs rapidly upon closure of the ductus arteriosus, without time for myocardial hypertrophy to develop. Thus, left ventricular afterload and wall stress increase in a relatively uncompensated fashion. Many factors, therefore, make the immature myocardium of infancy particularly vulnerable to the hemodynamic disturbances imposed by severe coarctation and explain the observation that systolic dysfunction and heart failure in coarctation are confined primarily to the first weeks of life.

Coarctation also may cause left ventricular diastolic dysfunction. Echocardiographic studies have demonstrated a decreased rate of early left ventricular diastolic relaxation, with consequent abnormalities in diastolic filling characterized by a shift of left ventricular filling into late diastole (27). These abnormalities in diastolic function are believed to relate to diminished left ventricular compliance caused by myocardial hypertrophy, myocardial fibrosis, and, in some patients, an increase in the inotropic state of the myocardium. An important functional consequence is an increase in left ventricular end-diastolic pressure at any given filling volume. Thus, left atrial hypertension and pulmonary venous congestion may occur, particularly in patients with an increased left ventricular end-diastolic volume.

The presence of an associated cardiovascular defect compounds the hemodynamic burden in some patients with a coarctation. Valvar or subvalvar aortic stenosis will increase the left ventricular systolic pressure and ventricular afterload further. A large ventricular septal defect, patent ductus arteriosus, or mitral regurgitation will increase left ventricular end-diastolic volume and ventricular preload. In concert with diminished left ventricular compliance, the augmented diastolic volume leads to an increase in left ventricular end-diastolic pressure. Subsequently, left atrial pressure will rise, and pulmonary venous and arterial hypertension may develop. Therefore, heart failure and pulmonary artery hypertension are relatively common in children with coarctation and associated aortic stenosis and/or ventricular septal defect as a consequence of disturbances in left ventricular preload, afterload, and diastolic function.

Abnormalities in vascular physiology also occur in patients with coarctation of the aorta. Systolic arterial hypertension is a manifestation of the aortic constriction, but it also reflects changes in vascular reactivity, arterial wall compliance, and baroreceptor reflex function. Studies of patients after coarctation repair have demonstrated abnormal arterial vascular function (28–30), as well as resetting of the baroreceptor reflex in some patients with persistent hypertension (31). Such abnormalities in arterial physiology, which may be present after successful anatomic relief of coarctation, help to explain the occurrence of systolic hypertension in some patients many years after coarctation repair.

CLINICAL FEATURES

The clinical presentation of coarctation generally follows one of three patterns: an infant with congestive heart failure, a child with a heart murmur, or a child or adolescent with systemic arterial hypertension. When coarctation manifests in infancy, it often presents as a catastrophic illness. Congestive heart failure and shock often occur suddenly as the ductus arteriosus closes. A large proportion of these infants have coarctation with important associated lesions such as a ventricular septal defect or aortic stenosis. In an infant with severe coarctation and a large ventricular septal defect, acute heart failure, shock, and acidosis classically develop suddenly around 8 to 10 days of life. Multiorgan system failure, particularly renal failure and/or necrotizing enterocolitis and death occur rapidly unless definitive medical and surgical interventions are provided immediately.

Coarctation of the aorta may present later in childhood as systolic upper extremity hypertension or as a heart murmur. Delayed diagnosis beyond infancy is common as physical findings may be subtle, and most of these patients are asymptomatic. On careful investigation, some will report lower extremity claudication with exercise or frequent headaches. In a review of children (older than 1 year) presenting with coarctation at Columbia University between 1969 and 1978, the median age at diagnosis was 10 years (32). The most common causes for referral were hypertension or a heart murmur. The correct diagnosis of coarctation was made by the referring physician in only 14% of cases.

Physical Examination

The general appearance of a child with coarctation will vary depending on the mode of presentation. In an infant with heart failure, one encounters a pale, irritable child in respiratory distress. Tachycardia, dyspnea, diaphoresis, hepatomegaly, and poor perfusion signal the presence of congestive heart failure and low cardiac output. Differential cyanosis may be observed (cyanosis confined to the lower extremities) if a right-to-left ductal shunt is present. In contrast, an older child with coarctation may appear entirely healthy. The characteristic findings of Turner syndrome are evident in some girls, and include short stature, widely spaced nipples, and a webbed neck. Not all girls with the Turner genotype manifest the phenotype.

The hallmark physical findings in coarctation consist of discrepant arterial pulses and systolic blood pressures in the upper and lower extremities. Arterial pulses below the coarctation are diminished in amplitude and delayed in timing compared with the proximal pulses (*pulsus parvus et tardus*). Systolic blood pressure is elevated proximal to the coarctation, and a systolic pressure gradient is present between the arm and leg. Several clinical circumstances may make detection of arterial pulse and pressure discrepancies difficult. First, the coarctation pressure gradient may be minimal, sometimes as a result of a mild coarctation, but also with heart failure and diminished cardiac output or with a large patent ductus arteriosus. Descending aorta flow may be maintained by a right-to-left ductal shunt and, in the presence of a large ventricular septal defect, the perfusion may be well oxygenated and pulsatile. Second, detection of arterial pulse and pressure differences may be difficult because of variations in brachiocephalic artery anatomy. An anomalous right subclavian artery arises distal to the coarctation in approximately 3% to 4% of cases. In these patients, the arterial pulse and blood pressure are identical in the right arm and leg, and discrepancies are detected only in the left arm. In other patients, the left subclavian artery arises adjacent to the coarctation, and its orifice may be stenotic. In such patients, a bounding arterial pulse and elevated systolic pressure will be detected only in the right arm. Rarely, patients may present with an anomalous right subclavian artery and a stenotic left subclavian artery. In these patients, arterial differences in the four extremities will not be detected, although carotid artery pulsations will be bounding.

Several findings may be noted on palpation of the precordium. Left ventricular pressure and volume overload may produce a prominent, heaving ventricular impulse at the apex. A prominent right ventricular impulse at the lower left sternal border or xiphoid area occurs if there is associated pulmonary hypertension. A systolic thrill may be palpable in the suprasternal notch, but the presence of a precordial thrill is unusual in isolated coarctation and should raise suspicion of an associated intracardiac lesion. If a robust collateral system exists, a common occurrence in older children and adolescents, prominent collateral artery pulsations may be palpable in the intercostal areas and/or between the scapulae posteriorly.

Auscultation generally reveals normal first and second heart sounds. A constant systolic ejection click may be heard at the apex, signaling the presence of a bicuspid aortic valve. Several murmurs may be present, depending on the nature of the coarctation, associated intracardiac lesions, and the arterial collateral system. A grade 2–3/6 systolic ejection murmur originating from the coarctation itself is usually best heard at the upper left sternal border, at the base, and in the left interscapular area posteriorly. If the coarctation is severe, this systolic murmur may be long and spill into diastole. The interscapular location of the murmur helps to identify the site of coarctation as the upper thoracic aorta. Continuous murmurs may be prominent throughout the chest anteriorly, laterally, and posteriorly in patients with a well-developed arterial collateral system. Associated intracardiac lesions create other murmurs. Aortic valve stenosis will produce a systolic ejection murmur at the upper right sternal border. A ventricular septal defect or mitral regurgitation will produce an S1-coincident holosystolic murmur at the lower left sternal border or apex. Associated mitral stenosis or a large left-to-right ventricular shunt will give rise to a mid-diastolic rumble at the apex. Finally, a gallop rhythm may be heard in an infant with congestive heart failure. If the cardiac output is severely diminished, murmurs may be subtle and the gallop rhythm may be the most prominent auscultatory finding.

Electrocardiographic Features

An infant presenting with coarctation of the aorta generally has a normal electrocardiogram (33). The finding of left ventricular hypertrophy in infancy, particularly with a strain pattern of ST segment and T-wave depression, strongly suggests associated aortic stenosis or primary myocardial disease. The electrocardiogram of older children and adolescents will reflect the effects of long-standing left ventricular pressure overload. Left ventricular hypertrophy and left atrial enlargement may be present. Associated intracardiac lesions will affect the electrocardiographic findings. The frontal-plane QRS axis may be left and anterior with associated atrioventricular septal defects, double-outlet right ventricle, or primary myocardial disease. Left ventricular hypertrophy with strain may indicate the presence of severe valvar or subvalvar aortic stenosis. Right ventricular hypertrophy that persists beyond infancy may indicate the presence of pulmonary hypertension resulting from associated lesions, such as a ventricular septal defect or mitral stenosis.

Radiologic Features

The chest roentgenogram of an infant with coarctation who presents with congestive heart failure is nonspecific. Moderate to severe cardiomegaly is evident, and the pulmonary vascular markings are increased. Pulmonary vascular congestion may be indistinct and passive in nature, related to left ventricular failure or mitral stenosis with pulmonary venous hypertension, or it may be active and related to increased pulmonary blood flow from a large left-to-right shunt. Rib notching is not present in infants because the collateral circulation is not yet well developed.

In older children and adolescents with coarctation of the aorta, the chest roentgenogram typically shows normal or only mildly enlarged heart size. The pulmonary vascular markings are normal unless there is an associated defect present. An abnormal contour of the aortic arch is common on the frontal film and consists of a localized indentation of the aorta at the site of coarctation (3 sign). Immediately below the 3 sign, the descending aorta may be prominent due to poststenotic dilation. Rib notching may be found in older patients. It is caused by erosion of the inferior surfaces of posterior ribs by dilated and tortuous intercostal arteries (Fig. 47.7). Rib notching may be unilateral if one subclavian artery is stenotic or arises distal to the coarctation.

Figure 47.7 Chest radiograph of a woman with unrepaired coarctation demonstrating rib notching from dilated and tortuous intercostal arteries.

Magnetic Resonance Imaging and CT Angiography

High-quality images of coarctation can be obtained by magnetic resonance imaging (MRI). MRI images in the sagittal and parasagittal projections can clearly define the location and severity of coarctation (Fig. 47.8), and the anatomy of the aortic arch. Information about the presence of a patent ductus arteriosus and the collateral arterial circulation also may be obtained. Three-dimensional surface rendering can provide exquisite anatomic detail in these patients (34). MRI studies are particularly suited to patients who require high-resolution

Figure 47.8 Magnetic resonance image in a sagittal projection demonstrating a discrete coarctation of the aorta just distal to the left subclavian artery. There is mild dilation of the descending aorta.

Figure 47.9 Three-dimensional reformatted CT angiogram in a left-lateral projection in a 19-month-old infant with a discrete coarctation and a tortuous, somewhat hypoplastic transverse arch and isthmus.

serial imaging, such as before and after surgical repair, angioplasty, or stenting (35). MRI studies can also provide an assessment of aortic flow, and can estimate pressure gradients (36). Multidetector CT angiography can also provide excellent anatomic diagnosis in patients with coarctation and aortic arch anomalies (Fig. 47.9). CT angiographic data are acquired very rapidly (typically in 4 to 5 seconds) as gating is not required as with MRI studies. Unlike MRI examinations, however, CT angiography does expose the patient to ionizing radiation.

Echocardiography

Two-dimensional echocardiography and Doppler studies provide an accurate, noninvasive assessment of coarctation anatomy and physiology in most patients. High-quality ultrasound images of coarctation can be obtained in infants but may be somewhat difficult to obtain in larger children and adolescents. From the suprasternal long-axis view, typical thoracic coarctation appears as a localized narrowing of the thoracic aorta just beyond the origin of the left subclavian artery (Fig. 47.10). The narrowing appears as a shelf of fibrous tissue protruding from the posterior aspect of the aorta and oriented toward the ductus arteriosus (the “posterior shelf”). Associated findings such as isthmus hypoplasia, poststenotic dilation, and diminished systolic pulsations in the descending aorta serve to confirm the presence of a significant coarctation. Color-flow Doppler assists in localizing the site of obstruction and is particularly helpful in cases where 2-D imaging is difficult or inconclusive.

Doppler echocardiography can assist in determining the hemodynamic severity of a coarctation. A continuous-wave Doppler study from the suprasternal window will detect high-flow velocity across the stenosis (Fig. 47.11). A peak instantaneous pressure gradient may be determined from the maximal flow velocity using the modified Bernoulli equation. The Doppler-flow display across the coarctation often demonstrates a pattern of diastolic runoff, particularly in patients with a severe stenosis or with a robust collateral circulation. The continuous wave Doppler flow profile across a coarctation is composed of two superimposed signals representing low-velocity flow in the proximal descending aorta (proximal to the coarctation) and higher-velocity flow across the coarctation itself. A corrected gradient is obtained by subtracting

Figure 47.10 Two-dimensional echocardiogram obtained in the suprasternal long-axis view demonstrating a discrete coarctation of the aorta. Aao, ascending aorta; Dao, descending aorta.

the proximal gradient (V1) from the gradient at the coarctation site (V2).

Two-dimensional and Doppler echocardiography is particularly important in evaluating intracardiac lesions that may be associated with coarctation. High-quality echocardiographic studies yield sufficient anatomic and physiologic data to enable the clinician to make a comprehensive diagnosis without the need for further diagnostic imaging in most patients.

Cardiac Catheterization and Angiography

Cardiac catheterization can serve both diagnostic and therapeutic purposes in patients with a coarctation. Diagnostic cardiac catheterization is unnecessary if noninvasive evaluation clearly delineates the lesions that are present. If important clinical questions remain regarding the nature and severity of a coarctation or possible associated intracardiac lesions, a diagnostic cardiac catheterization may be performed. The objectives of a diagnostic cardiac catheterization in a patient with coarctation are to define the anatomy and severity of the coarctation, the nature of the arterial collateral circulation, the presence and severity of associated lesions, left ventricular function, and pulmonary artery pressure and resistance.

The hemodynamic severity of a coarctation often is assessed by the magnitude of the systolic pressure gradient. Coarctation causes an elevated systolic pressure and pulse pressure within the ascending aorta and a diminished systolic pressure and pulse pressure in the descending aorta (Fig. 47.6). In a child with an isolated coarctation and a normal cardiac output, a systolic gradient <20 mm Hg is often indicative of mild coarctation. However, pressure gradient alone may underestimate the hemodynamic importance of a coarctation. The pressure gradient may be diminished with left ventricular dysfunction and low cardiac output, by a large patent ductus arteriosus, by multiple left-sided obstructive lesions in series, or by a well-developed collateral circulation that decompresses the ascending aorta. Thus, the hemodynamic importance of a measured coarctation gradient must be assessed in the context of the patient's overall anatomy and hemodynamic status.

Angiography remains a gold standard for evaluating coarctation and aortic arch anatomy. The anatomy of the coarctation and collateral circulation generally is best imaged by an ascending aortogram filmed in the anteroposterior and straight lateral projections. In some patients, the anteroposterior camera is rotated 10 to 15 degrees left anterior oblique

Figure 47.11 Typical continuous-wave Doppler display across a severe coarctation. The peak velocity is 3.4 m/s. Note the diastolic runoff pattern consistent with a pressure gradient throughout diastole.

(LAO) to unwrap the ascending from the descending aorta. If the ascending aorta is not catheterized, the coarctation anatomy may be visualized satisfactorily in some patients with a left ventricular angiogram alone.

TREATMENT

Untreated coarctation of the aorta has a poor natural history. In his classic 1970 study, Campbell reported natural history data obtained from necropsy and clinical records on 465 patients with coarctation (37). Only subjects who survived the first year of life were evaluated, thus excluding infants with critical coarctation and congestive heart failure. Nevertheless, Campbell's natural history data for untreated coarctation beyond infancy documented a mean age at death of only 34 years (median, 31 years); 75% of patients died by 46 years of age. The most common causes of death were congestive heart failure (26%), aortic rupture (21%), bacterial endocarditis (18%), and intracranial hemorrhage (12%). Given such a poor prognosis untreated, it is apparent that intervention is indicated in virtually all patients with coarctation of the aorta. The timing of therapy depends on the nature of the patient's presentation.

Presentation in Infancy

Coarctation presenting with heart failure in infancy requires immediate and aggressive treatment. Medical management consists of initially stabilizing the patient with inotropic support and diuretic therapy. A critically ill newborn also may benefit from prostaglandin E1 to promote ductal patency and improve perfusion of the descending aorta, renal, and mesenteric beds (38). Metabolic disturbances, such as acidosis, hypothermia, hypoglycemia, or anemia must be treated promptly. After a brief period of medical management to stabilize the child, definitive repair should be performed (39). In experienced centers, the mortality rate for surgical repair of isolated coarctation in infancy is extremely low (40–47).

The surgical risks are higher for infants with coarctation who have associated major intracardiac anomalies. Nevertheless, after a period of medical stabilization, early repair of the coarctation also is indicated in these children. The surgical mortality rate for these infants ranges from 2% to 10% and is highest for children with the most complex intracardiac defects (40–43,45). The need for intracardiac repair (or pulmonary artery banding) at the time of coarctation repair is not always clear. In some circumstances, coarctation repair alone is sufficient and actually may improve the pathophysiology of the associated lesion. For example, following repair of coarctation an infant with a ventricular septal defect may demonstrate a diminished left-to-right shunt and resolution of congestive heart failure. Subsequently, some will experience spontaneous diminution in size of the ventricular septal defect sufficient to avoid future intracardiac surgery. Modest hypoplasia of the aortic or mitral valves may improve in follow-up after surgical repair of the coarctation in the newborn period (48). Intracardiac repair at the time of coarctation repair is appropriate in infants with a large ventricular septal defect or with a more complex lesion such as D-transposition with ventricular septal defect or double-outlet right ventricle. A single-stage, anterior approach to complete repair in newborns with coarctation and intracardiac anomalies is an effective and relatively safe option in many centers (49,50).

Presentation in Childhood

Coarctation more commonly presents in childhood or adolescence as upper extremity hypertension and/or a heart murmur, but without overt symptoms. The timing of coarctation repair in this setting is relatively elective. Coarctation repair is commonly recommended at 1 to 3 years of age in asymptomatic children without severe upper-extremity hypertension. This practice is based on several considerations. First, the risk for late recurrence of coarctation appears to be increased when repair is performed on patients under 1 year of age (40–42,51–54). The influence of age at repair on restenosis is explained in part by the smaller diameter of

the surgical anastomosis when repair is performed in younger children (55). Second, even in the absence of residual stenosis, there is an increased risk for persistent hypertension and early atherosclerotic cardiovascular disease if coarctation repair is delayed into late childhood and adolescence (56). In a long-term follow-up study of 234 patients, the prevalence of residual hypertension was 6% in patients who underwent coarctation repair between 1 and 5 years of age compared with 30% to 50% in patients whose coarctation was repaired at an older age (57). An informative retrospective follow-up study (54) used multivariate analysis to assess influence of age at operation on composite outcomes of survival, residual hypertension, and recurrent stenosis. The study concluded that these outcomes are optimized if elective coarctation repair is performed at approximately 1.5 years of age.

Surgical Repair

Many surgical techniques have been used to repair aortic coarctation, and each has advantages and disadvantages. Surgical approaches to coarctation include resection and end-to-end anastomosis, subclavian flap aortoplasty, prosthetic patch aortoplasty, and bypass grafts between the ascending and descending aorta. Regardless of the technique, surgical coarctation repair generally is performed through a left lateral thoracotomy incision. If necessary, as when combined with repair of an intracardiac lesion, coarctation repair can be performed from an anterior approach. Regardless of the surgical technique used, most children with a discrete coarctation will have a residual resting systolic pressure gradient under 10 to 15 mm Hg immediately after repair.

The mortality rate for surgical coarctation repair varies depending on patient age and associated lesions. The surgical mortality for repair of isolated coarctation in infants and older children currently approaches 0% (45,46,58), rises to 2% to 10% for infants with an associated large ventricular septal defect, and is higher in the presence of more complex intracardiac lesions. Surgical morbidity includes postoperative paradoxical hypertension, spinal cord ischemia and paralysis, recurrent laryngeal or phrenic nerve injury, chylothorax, bleeding, and infection. Paradoxical hypertension (the postcoarctectomy syndrome) may occur during the first 2 to 5 days following coarctation repair, with systolic and diastolic pressures rising above pretreatment levels (59). In severe cases, mesenteric arteritis and bowel ischemia may develop. The mechanism is related to rebound activation of the sympathetic nervous system and the renin-angiotensin system with mesenteric arterial vasoconstriction. Postoperative paradoxical hypertension can be prevented with beta-blocker therapy (60) and by aggressive antihypertensive therapy during the immediate postoperative period. Spinal cord injury and subsequent paralysis may occur if aortic cross-clamping severely compromises perfusion to the descending aorta and spinal arteries. This rare complication appears to be limited to patients with a poor arterial collateral circulation. It is avoided by ensuring adequate descending aorta perfusion when the aorta is cross-clamped, limiting total cross-clamp time to under 30 minutes, minimizing the number of intercostal arteries sacrificed, avoiding hyperthermia, and using hypothermia if necessary (61). Left heart bypass may be necessary in some patients to maintain adequate descending aorta perfusion when the aorta is cross-clamped.

Reoperation for postoperative residual or recurrent coarctation is technically more difficult and carries a higher risk for morbidity and mortality than initial surgery for native disease (51,52). The surgical techniques used have included prosthetic or subclavian patch aortoplasty, bypass grafts from the ascending to descending aorta, and less commonly simple resection. Residual coarctation gradients and upper-extremity hypertension may persist postoperatively in a substantial

Figure 47.12 Coarctation resection and end-to-end anastomosis. The circumferential anastomosis is completed with interrupted sutures anteriorly.

portion of patients. The reported experience with reoperation, which is less satisfactory than initial surgery for native coarctation, is explained in part by patient selection. Patients requiring reoperation are older and more likely to have complex arch anatomy, such as long-segment coarctation or arch hypoplasia, compared with patients undergoing initial repair.

Surgical repair of coarctation of the aorta was first reported in 1945 by Crafoord and Nylin (62), who described the technique of resection and end-to-end anastomosis (Fig. 47.12). In most centers, this procedure remains the surgical treatment of choice for patients with a discrete coarctation. An extended end-to-end anastomosis using a broader longitudinal incision across the proximal aorta (Fig. 47.13) improves the effectiveness of this operation in infants with hypoplasia of the isthmus or transverse arch (63), and has decreased the risk of late restenosis (45,46,58). The advantages of resection include removal of the coarcted segment and adjacent areas of ductal tissue, avoidance of prosthetic materials, and sparing the left subclavian artery in most instances. Disadvantages of resection relate primarily to the presence of a circumferential suture line, which led to a high incidence of restenosis in early studies. The use of interrupted and absorbable sutures anteriorly and an extended anastomosis in patients with isthmus or arch hypoplasia have improved clinical outcomes after resection in more recent studies (45,46,49,58,63).

Prosthetic patch aortoplasty was the second surgical technique described for coarctation repair, by Vosschulte in 1961 (64). A longitudinal incision is made across the coarctation, if necessary extending onto the proximal left subclavian artery and the area is enlarged with a patch of Dacron or Gore-Tex (Fig. 47.14). The posterior shelf of the coarctation may or may not be resected. Compared with coarctation resection, patch aortoplasty has the advantages of requiring less extensive aortic mobilization, preserving intercostal arteries, and avoiding a circumferential suture line. Patch aortoplasty also can be used for some long-segment coarctations. The disadvantages of this technique include the use of prosthetic material and a relatively high incidence of late aortic aneurysm formation (34,65–67).

Figure 47.13 Resection with an extended end-to-end anastomosis. The anastomosis extends onto the transverse arch under the left common carotid.

The subclavian flap aortoplasty procedure was introduced in 1966 by Waldhausen and Nahrwold (68) in an attempt to improve on the high rates of restenosis originally reported following resection. The left subclavian artery is ligated and divided, and a longitudinal incision is extended through the proximal subclavian artery and beyond the coarctation. The proximal subclavian stump then is turned down onto the coarctation and used as a patch of autologous tissue (Fig. 47.15).

Figure 47.14 Prosthetic patch aortoplasty repair of coarctation.

Figure 47.15 Left subclavian flap aortoplasty repair of coarctation.

The vertebral artery is ligated to avoid subclavian steal. The subclavian flap procedure has the advantages of requiring less extensive aortic mobilization, avoiding prosthetic materials, using living subclavian tissue as a patch with theoretical growth potential, and avoiding a circumferential anastomosis. It also can be used for some long-segment coarctations and coarctation associated with isthmus hypoplasia. An obvious disadvantage is that the procedure requires sacrifice of the left subclavian artery. Early studies suggested that the subclavian flap operation was the treatment of choice for infants with coarctation because of an apparent reduction in the incidence of late restenosis. More recent studies, however, failed to confirm this advantage (40,41,53). Therefore, because of the occasional untoward effects on the left upper extremity (69,70) many centers prefer resection if the anatomy is suitable.

Percutaneous Balloon Angioplasty and Stenting

Percutaneous balloon angioplasty is a less invasive alternative to surgical repair for patients with a discrete coarctation of the aorta. Balloon angioplasty has gained wide acceptance as effective therapy for a recurrent postoperative coarctation, but remains controversial as a primary treatment strategy for a native coarctation. The mixed reception for this less invasive procedure is best understood by considering the surgical alternatives. Surgical repair of an isolated native coarctation carries low risks and a high expectation of success. In contrast, reoperation for recurrent postoperative coarctation is technically more difficult and is associated with increased morbidity and mortality.

Balloon angioplasty has been used for coarctation since 1982, and a modest literature documents angioplasty safety and effectiveness in patients with a native coarctation (71–77) and with recurrent postoperative coarctation (78–84). The balloon dilation procedure typically is performed in a retrograde fashion from the femoral artery, although the antegrade transvenous approach may be used, and is particularly suitable in infants following the Norwood procedure (83).

The mechanism by which balloon angioplasty relieves coarctation stenosis has been elucidated in several postmortem

Figure 47.16 Angiograms in the lateral projection before (A) and immediately after (B) balloon angioplasty of a native coarctation in a 3-year-old girl. Prior to angioplasty (A) there is a severe discrete coarctation completely occluded by the catheter. Immediately after angioplasty (B), the aortogram documents improvement in the stenosis, with an intimal irregularity anteriorly. Two years later, CT angiography documented an excellent anatomic outcome without aneurysm. There was no residual pressure gradient in follow-up.

and experimental studies (85–88). Angioplasty enlarges the coarctation lumen by expanding the lesion diameter and producing linear intimal and medial tears at the coarctation site (and in the normal distal aorta as well). In most instances, the medial tears are shallow, but rarely some may extend to the adventitia. Histologic evaluation in animal models have shown vascular healing to have occurred by 8 weeks after angioplasty (88).

Angioplasty for Native Coarctation

The acute effectiveness of balloon angioplasty for discrete native (unoperated) coarctation has been demonstrated in numerous studies (Fig. 47.16). The early multicenter report from the Valvuloplasty and Angioplasty of Congenital Anomalies (VACA) Registry (71) described the procedure in 140 patients whose age ranged from 3 days to 29 years. Angioplasty acutely decreased the systolic gradient from 48 to 12 mm Hg, with an increase in the coarctation diameter from 3.9 to 8.8 mm. A residual gradient exceeding 20 mm Hg was reported in 14% of the patients. In a follow-up study of 59 children ≥ 2 years after native coarctation angioplasty, repeat cardiac catheterization found a residual systolic gradient of ≥ 20 mm Hg or more in 27% of patients (75); in the remaining patients, the mean residual systolic gradient was 6 mm Hg (median gradient 8 mm Hg). A more recent long-term follow-up study (up to 22 years) in 58 patients reported similar late effectiveness (77).

Angioplasty of native coarctation has not gained wide acceptance because of concerns related to residual or recurrent stenosis and to aneurysm formation at the dilation site. It is difficult to discern the difference between residual and recurrent stenosis in many reports. Published data suggest that the incidence of a residual gradient exceeding 20 mm Hg ranges from 8% to 27% (71,75,77). Recurrent stenosis after an initially successful angioplasty appears to be uncommon during intermediate-term

follow-up in children and adolescents, but is relatively common in infants younger than 6 months of age (73–76,89). The incidence of aneurysm formation at the dilation site varies widely in published reports, possibly reflecting varying definitions of an aneurysm. The larger follow-up studies suggest that the incidence of aneurysm formation is approximately 5% to 10% (75–77). An aneurysm was identified in three of 59 children (5.1%) in our angiographic follow-up study ≥ 2 years after angioplasty. Serial angiography showed no progression in aneurysm size in two of these children over a 2- and 6-year period (75). In Fletcher's series of 102 patients, an aneurysm was identified in only 2 patients (1.9%), but longer follow-up for possible late aneurysm development was advised (76).

A number of acute complications has been reported with balloon angioplasty of native coarctation of the aorta. Mortality is rare beyond the newborn period. In the VACA Registry, one death (a neonate) was reported in 140 cases, yielding a mortality rate of 0.7% (71). The most common acute complication has been femoral artery injury. This appears to be more common in infants under 12 months of age and has decreased in frequency with the development of smaller angioplasty catheters (90). Other less common complications have included femoral artery hemorrhage requiring transfusion and cerebrovascular accident. Paradoxical hypertension is uncommon following percutaneous balloon angioplasty of coarctation (91).

Angioplasty for Recurrent Postoperative Coarctation

The acute effects of balloon angioplasty for recurrent postoperative coarctation are similar to those reported for native coarctation. The VACA Registry reported data on 200 patients undergoing balloon angioplasty for recoarctation (79). The systolic gradient decreased acutely from 42 to 13 mm Hg, and the diameter of the recurrent coarctation increased from 5.2 to 8.9 mm. Residual pressure gradients exceeding 20 mm Hg

were present in 20% of the patients. Similar outcomes have been reported from several centers (78–84). In general, the type of prior surgical repair has not affected angioplasty outcomes.

Follow-up data from several centers have addressed the longer-term effectiveness of balloon angioplasty for recurrent coarctation (80–82,84). As with native coarctation, restenosis does occur after angioplasty of postoperative recoarctation. Yetman et al. (81) reported follow-up data of 3 to 144 months (median, 39 months) in 74 patients with a good early result of angioplasty. Nineteen (26%) patients had repeat angioplasty or surgery for recurrent stenosis. Hypoplasia of the transverse aortic arch was the best predictor of the need for later reintervention. The incidence of aneurysm formation after balloon dilation of recurrent coarctation appears to be similar to that reported after native coarctation angioplasty (81,82,84).

Acute complications of balloon angioplasty for recurrent postoperative coarctation are similar to those for native

coarctation, although the reported mortality rate has been somewhat higher. Five deaths occurred among the 200 patients with recoarctation reported by the VACA Registry, giving a mortality rate of 2.5% (79). One death was caused by aortic rupture, and one was related to a cerebrovascular accident. The remaining three deaths were believed to be related to the associated cardiac disease. Other complications include femoral artery thrombosis, rare paradoxical hypertension, and transient neurologic events.

Coarctation Stenting

Balloon-expandable stents provide an effective therapy for many patients with coarctation of the aorta (Fig. 47.17). A stent implanted concurrently with balloon angioplasty functions as an endovascular buttress to support the dilated

Figure 47.17 Angiographic images in a slight LAO projection before (A), during (B), and immediately after (C) coarctation stenting in a 15-year-old girl with a native coarctation. The systolic pressure gradient was reduced from 40 to 0 mm Hg immediately after the stent procedure.

aortic segment. Stents decrease coarctation restenosis related to vessel recoil and may also diminish the late incidence of aneurysm formation. Covered stents may provide important added safety for patients with a vulnerable aortic wall, as in Turner syndrome or older adult patients.

The safety and effectiveness of percutaneous stent therapy for native or recurrent coarctation have been documented in numerous clinical series (92–101). Stenting provides very effective relief of stenosis and generally decreases the resting systolic gradient to <5 mm Hg in patients with a discrete coarctation. Furthermore, stent therapy may be beneficial in some patients with transverse arch hypoplasia as well (102). Several studies with modest intermediate-term follow-up data suggest that restenosis is uncommon following coarctation stenting. Stents implanted in growing children, however, are likely to require redilation to a larger diameter when the children grow. For this reason, even in children it is important to implant stents with a diameter potential suitable for the adult aorta.

Late aneurysm formation at the coarctation site may occur after stenting, but seems to be less frequently encountered than after balloon angioplasty alone. The primary use of covered stents may decrease the aneurysm risk further, and may be particularly valuable in patients with a very small coarctation lumen (<3 mm) or with increased aortic wall fragility (e.g., genetic syndromes, advanced age) (103). Larger follow-up studies are necessary to more precisely quantify the risk of aneurysm formation in patients who have undergone coarctation stenting, with either bare-metal or covered stents.

PROGNOSIS

The prognosis for a normal life following successful repair of coarctation in childhood is excellent. Normal growth and development are to be expected, and only minimal restrictions should be placed on physical activity. In treated patients without a significant residual systolic gradient (<10 mm Hg at rest), with normal upper-extremity blood pressure at rest and with exercise, and without an aortic aneurysm or significant associated intracardiac lesions, participation in sports is generally permitted with the exception of activities with a high static (isometric) component (104).

Nevertheless, the long-term prognosis after coarctation treatment may be affected by a number of clinical and hemodynamic conditions (Table 47.1). Residual or recurrent coarctation may occur, particularly after repair in infancy, regardless of whether the primary treatment was surgery or balloon angioplasty. The term *residual coarctation* implies the presence of an aortic arch gradient immediately after repair. The causes include inadequate repair of the coarctation and/or hypoplasia of the isthmus or transverse aortic arch. There is evidence to suggest that the transverse aortic arch may grow in some children following coarctation repair in infancy (105). The term *recurrent coarctation* implies the development of restenosis after an initially successful repair. Recurrent coarctation most commonly occurs because of inadequate growth at the coarctation repair site, consistent with the observation that recurrent coarctation is uncommon if surgical repair is performed after a child is 2 years of age. More recent surgical experience suggests that the use of an extended end-to-end anastomosis in infants may substantially decrease the risk of late recurrent coarctation (45,46). Residual and recurrent coarctations after balloon angioplasty also occur more commonly when the procedure is performed in infancy. Recurrence of stenosis is likely to occur with somatic growth after coarctation stenting in childhood, and will commonly require stent redilation to a larger diameter.

TABLE 47.1

Clinical and Hemodynamic Conditions that May Affect Long-Term Prognosis after Repair of Coarctation

Residual or recurrent coarctation
Hypertension (rest and exercise)
Aortic aneurysm
Aortic dissection
Intracranial hemorrhage
Diminished left arm growth/subclavian steal
Endocarditis/endarteritis
Associated intracardiac lesions

The long-term prognosis following repair of coarctation may be adversely affected by systemic arterial hypertension and an increase in premature atherosclerotic cardiovascular events (56,106). Even in the absence of a residual coarctation gradient, patients may exhibit late systolic and diastolic hypertension. This is most common in patients whose coarctation repair is delayed beyond late childhood. The risk for late hypertension may be as high as 10% to 20% however, even if a coarctation is repaired in infancy (54,107). The etiology of late postoperative hypertension in patients without a residual coarctation gradient may relate to anatomic and functional changes in the arterial vasculature. Animal studies document abnormal intimal thickening and medial hypertrophy in the proximal aortic arch late following successful relief of experimental coarctation (108). Such morphologic changes would be expected to decrease arterial compliance and provide an anatomic basis for the functional abnormalities in vascular reactivity and baroreceptor function that have been reported following coarctation repair (28,30,31,109). Systolic hypertension after coarctation repair also may occur during dynamic exercise, even in patients without resting hypertension or a resting coarctation gradient (110). Although alterations of vascular physiology may play a role, exercise-induced upper-extremity hypertension often is associated with an increase in the coarctation pressure gradient during exercise. The increase in blood flow across a relatively nondistensible aortic repair site that occurs with dynamic leg exercise may be primarily responsible for exercise-induced elevations in coarctation gradient and upper-extremity systolic pressure following coarctation repair. Patients with exercise hypertension, but without a significant residual coarctation gradient at rest, may benefit from beta-blocker therapy (111).

An aortic aneurysm may develop at the site of surgical coarctation repair (Figs. 47.18 and 47.19). The incidence of postoperative aortic aneurysm is highest following prosthetic patch aortoplasty (65–67), although aneurysms have been reported following other surgical procedures as well. In a prospective study, the presence of an aortic aneurysm was documented in 24% of patients evaluated 1 to 19 years after patch aortoplasty repair of coarctation (65). Once present, such aneurysms may progress rapidly and may be responsible for aortic rupture and sudden death (112). Aortic aneurysms also occur following balloon angioplasty of coarctation and have been largely responsible for the reluctance of some cardiologists to recommend angioplasty for a native coarctation. The risk of aortic aneurysm following coarctation angioplasty

Figure 47.18 Chest radiograph 3 years (left panel) and 8 years (right panel) after prosthetic patch aortoplasty repair of coarctation, documenting progressive aneurysmal dilation at the repair site. (Reprinted from Mendelsohn AM, Crowley DC, Lindauer A, et al. Rapid progression of aortic aneurysms after patch aortoplasty repair of coarctation of the aorta. *J Am Coll Cardiol* 1992;20:381–385, with permission from Elsevier.)

varies widely in published reports, with the larger follow-up studies estimating its incidence to be approximately 5% to 10% (75–77). Late aneurysms may occur less commonly after coarctation stenting (Fig. 47.20), particularly if a covered stent

is employed primarily, but more follow-up data are necessary to precisely define this risk.

Other vascular abnormalities that affect long-term outcomes in some patients after coarctation repair include aortic dissection, intracranial hemorrhage, and diminished left arm growth or subclavian steal syndrome. Aortic dissection may occur with or without the presence of an aortic aneurysm at the coarctation repair site. Factors predisposing to dissection include cystic medial necrosis of the aortic wall, atherosclerosis, persistent arterial hypertension, and dilation of the ascending aorta, which is particularly common in patients with Turner syndrome. Intracranial hemorrhage may occur late following coarctation repair, with or without associated hypertension, and may be related to the presence of berry aneurysms in the circle of Willis. Cerebrovascular accidents have been an important cause of late morbidity in the larger studies of long-term coarctation outcomes (56,113). Procedures such as left subclavian flap aortoplasty that sacrifice the subclavian artery may be responsible for detrimental long-term effects. Late studies following subclavian flap aortoplasty documented diminished arterial blood supply to the left arm with a diminished reactive hyperemia response (69). These patients may experience arm claudication with exercise and diminished growth of the left arm (40,69,70). The subclavian steal syndrome may occur if the vertebral artery remains intact distally.

Bacterial endocarditis or endarteritis is responsible for important morbidity in some patients with coarctation of the aorta. Endocarditis may occur on a bicuspid aortic valve or other associated intracardiac lesions. Endarteritis typically occurs at or just distal to the site of coarctation repair in the area of turbulence and intimal thickening and has resulted in mycotic aneurysms in some patients.

Finally, the long-term prognosis after coarctation repair may be affected by the presence of associated intracardiac lesions such as aortic or mitral valve disease (106). Patients who required repair of associated intracardiac defects earlier in life (e.g., ventricular septal defect (VSD) closure) may have long-term issues related to a residual VSD, postoperative heart block, or progressive left ventricular outflow obstruction. Such patients require lifelong cardiology follow-up and surveillance for the late evolution of residual postoperative lesions and sequelae of therapy.

Figure 47.19 Large (65 × 76 mm) aortic aneurysm in a 28-year-old patient 16 years after prosthetic patch repair of coarctation. The anatomy of the arch and aneurysm are delineated by a 3-D surface rendered image reconstructed from a magnetic resonance angiography study. (Courtesy of W. James Parks, M.D., The Children's Heart Center, Emory University, Atlanta, GA.)

Figure 47.20 Moderate saccular aneurysm 8 months after bare-metal stenting of a severe native coarctation in a 16-year-old boy (A). After implantation of a covered stent (B), the aneurysm was completely excluded from the aortic lumen. There was no residual coarctation gradient.

EPIDEMIOLOGY AND ETIOLOGY

Hypoplastic left heart syndrome (HLHS) makes up 1.4% to 3.8% of congenital heart disease, an incidence of 0.016% to 0.036% of live births. Despite this low incidence, HLHS causes 23% of cardiac deaths during the first week of life and 15% of cardiac deaths within the first month of life (1–6). A male predominance has been reported for HLHS (55% to 67%) (1,2,7–9).

While no gene abnormality is specific to HLHS, there is strong evidence supporting a genetic etiology for HLHS. The recurrence risk in families with one affected child is 0.5% to 2%. Additionally, the recurrence risk for other forms of congenital heart disease in families with one affected child with HLHS is 2.2% to 13.5% (10–12). In addition, pedigree analyses have demonstrated a 12% prevalence of cardiac abnormalities involving the left ventricular outflow tract in first-degree relatives of patients with HLHS (13,14). Lewin et al. (15) studied 278 first-degree relatives of 113 patients with nonsyndromic left ventricular outflow obstruction and found that 4.6% had a bicuspid aortic valve; an additional 11.5% of relatives had anomalies of the aorta, aortic valve, left ventricle (LV), or mitral valve (MV).

Extracardiac anomalies and genetic syndromes have been recognized in patients with HLHS with a reported incidence of 15% to 30% (16–19). Identified heritable syndromes associated with HLHS include Kabuki syndrome, Noonan syndrome, Smith-Lemli-Opitz syndrome, Holt-Oram syndrome, Ellis-van Creveld syndrome, oral-digital-facial syndrome, and CHARGE syndrome (1,20–27). Additionally, several chromosomal abnormalities have been identified in patients with HLHS, including Turner syndrome, trisomy 13, trisomy 18, trisomy 21, duplication of short arm of chromosome 12, 2q-, a balanced 3:7 translocation, 4q-, 4p-, 7q-, 11q- (Jacobsen Syndrome), duplication of 16q, and 18p- (1,25,28). Mutations have been implicated in specific genes including GJA1 (Connexin Protein 43), NKX2-5, NOTCH1, and HAND1 (29–33). Linkage analyses have suggested additional loci on chromosomes: 2p23, 10q21, 16p12, 2p15, 10q22, and 6q23 (34–36). Future work in molecular genetics may allow determination of the cause of HLHS and will be assisted by population registry information, tissue banking, and improved gene sequencing technology.

Environmental factors have been implicated in the development of HLHS. The Baltimore-Washington Study identified a geographic cluster of HLHS in a region of Baltimore characterized by industrial land use and release of solvents, polychlorinated biphenyls, and dioxin into air (37). Environmental factors were also implicated in a study finding an increased incidence of HLHS in southeastern Wisconsin (38). A link between maternal group A beta-hemolytic streptococcal pharyngeal infection and HLHS has been suggested (39). Antibodies formed from Streptococcal pharyngitis cross the placenta

and are associated with injury to the developing left ventricular outflow tract of the fetus resulting in HLHS. A recent study found a seasonal occurrence to HLHS again implicating an infectious–environmental cause (40).

THE DEVELOPING FETUS: ECHOCARDIOGRAPHY AND INTERVENTION

Prior to the advent of fetal echocardiography, the embryologic cause of HLHS was not entirely clear. However, with advances in fetal cardiac imaging, it became evident that many forms of congenital heart disease evolve throughout gestation. In 1989, Allan et al. (41) observed the in utero evolution of HLHS in a fetus initially diagnosed with critical aortic stenosis. A similar case report was published by Danford and Cronican (42) in 1992. Since that time, several fetal cardiac centers have reported retrospective collaborative data that suggest that serial measurements of left heart growth and assessment of flow direction across the foramen ovale and distal aortic arch may identify fetuses at risk for severe left heart hypoplasia at term (42–45). It is now postulated that many cases of HLHS are dynamic and progressive throughout gestation, resulting from altered left ventricular outflow (aortic stenosis) or altered left ventricular inflow (MV stenosis/foramen ovale restriction/alterations of atrial septal anatomy) (46–48). The field of prenatal cardiac intervention is under way, and early successes with balloon dilation of the aortic valve led to investigations as to whether the development and incidence of HLHS at term can be altered (49).

Fetal Echocardiography

Recent advances in 2-D and Doppler echocardiography have made it feasible to diagnose all forms of congenital heart disease in the fetus. HLHS is one of the most common structural lesions diagnosed prenatally, as a screening obstetric ultrasound will preferentially identify lesions that dramatically alter the four-chamber view (50–52) (Fig. 48.1). The prenatal diagnosis of HLHS is easily made when a small, muscle-bound left ventricular chamber is identified. The challenge for the fetal echocardiographer today is to recognize the potential for the evolution of HLHS, especially since some of these patients may be candidates for prenatal intervention. Another challenge is to diagnose the severely restrictive or intact atrial septum in this patient group prior to birth, as these patients have a particularly dismal outcome and may also benefit from prenatal intervention.

The fetal LV is predominantly filled with oxygenated blood that returns from the placenta and traverses the foramen

FIGURE 48.1. Fetal echocardiogram demonstrating HLHS. Screening obstetric ultrasound will preferentially identify lesions that dramatically alter the four-chamber view. The left ventricular chamber size is small compared with the RV. The lining of the LV is echobright, indicative of endocardial fibroelastosis. LV, left ventricle; RA, right atrium; RV, right ventricle.

ovale (53). If blood flow across the foramen ovale is diminished or reversed, the combined cardiac output is redistributed to the right ventricle (RV) and pulmonary artery (PA), resulting in enlargement of the right heart structures and creating less impetus for normal growth of left heart structures, possibly evolving into HLHS. Perhaps the most well-recognized mechanism for decreased flow or reversal of flow through the foramen ovale in utero is the presence of severe aortic valve disease (41–45). With significant aortic valve stenosis, alterations in left ventricular compliance may occur, either secondary to the development of left ventricular hypertrophy or secondary to the development of left ventricular dilation and dysfunction. Endocardial fibroelastosis, a poorly understood phenomenon where the endocardial lining of the LV becomes fibrotic, may also be present. As the disease state progresses, with subsequent elevation in left atrial pressure, flow across the foramen ovale becomes bidirectional and eventually left to right, the result of which may be the cessation of left ventricular growth (54). In a classic study by Hornberger et al. (44), the prenatal and postnatal echocardiograms of 21 fetuses with left heart obstructive lesions were reviewed to identify possible prenatal indicators of postnatal disease severity. Prenatal indices that correlated with HLHS at birth included a smaller MV and ascending aorta in the midtrimester, as well as a decreased rate of growth for all left heart structures. Other prenatal features included reversal of flow across the foramen ovale and retrograde ductal supply of the distal aortic arch. In a more recent study, Makikallio et al. (55) reviewed the natural history of aortic stenosis in 43 fetuses initially referred prior to 30 weeks gestation. At the time of the initial examination, the LV:RV length ratio was $>0.8:1$, and aortic stenosis was the dominant lesion. The presence of moderate left ventricular dysfunction, retrograde transverse aortic arch flow, left-to-right atrial-level shunting, and a monophasic mitral inflow on the initial prenatal echocardiogram were found to be risk factors for the development of HLHS. Again, in this study there was decreased rate of growth of all left heart structures in those patients who developed HLHS. Based on these two series, it is now clear that the fetus with aortic stenosis is at risk for the development of HLHS. Serial echocardiographic follow-up is indicated in these fetuses, paying particular attention to growth of left heart structures and patterns of blood

flow across the foramen ovale and transverse aortic arch. Importantly, it now seems feasible to reliably select fetuses for prenatal intervention, using both anatomic and physiologic markers.

Although the operative survival for infants born with HLHS has improved significantly over time, the subgroup of patients with a highly restrictive or intact atrial septum continues to experience a higher mortality (56,57). These infants can be profoundly cyanotic at the time of delivery and are often unresponsive to medical intervention. Even with prompt resuscitation and adequate decompression of the atrial septum, there is ongoing morbidity and mortality, likely related to secondary anatomic changes in the lung. Some investigators have reported “arterialization” of the pulmonary veins and lymphatic dilation in this setting; others have postulated that there is associated PA hypoplasia. The ability to diagnose a restrictive atrial septal defect prior to birth would allow for more accurate prenatal counseling and planning immediate postnatal intervention. Theoretically, prenatal catheter intervention in this subgroup of patients may alter the secondary anatomic changes in the lung, possibly improving long-term outcome. For all of these reasons, routine evaluation of the atrial septum should be performed in all fetuses with HLHS. Direct assessment of foramen ovale size has not correlated well with the degree of left atrial hypertension at the time of birth, likely a reflection of the inability to clearly visualize the defect, which often lies more superiorly and posteriorly in the left atrium (LA) (58). Doppler interrogation of the pulmonary veins is technically much simpler, and the pattern of pulmonary venous flow in HLHS has correlated well with left atrial hemodynamics (58,59). The normal fetal pulmonary vein flow pattern consists of forward flow in systole and diastole, with cessation of flow or a small reversal wave with atrial systole. In a study by Taketazu et al. (58), a pattern of pulmonary vein flow with brief forward and reverse flow with minimal early ventricular diastolic flow was associated with the need for immediate respiratory support and emergent atrial decompression. Two of the three patients with this abnormal flow pattern died after neonatal heart transplantation, and the postmortem lung tissue analysis was notable for dilated lymphatic vessels, pulmonary vein arterialization, and abnormal PA musculature.

Fetal Intervention

It is important to remember that most fetuses with severe left ventricular outflow tract obstruction (LVOTO) will survive gestation. Therefore, fetal cardiac intervention in this setting does not serve as a lifesaving procedure but rather a procedure that may improve postnatal surgical options and outcomes. More specifically, it is hoped that successful intervention in the fetus with LVOTO will lead to a biventricular circulation at the time of birth. This possible benefit must be weighed against the risks of the procedure, which, even in the setting of technical success, may result in fetal death or extreme prematurity. Since the risk/benefit ratio of fetal cardiac intervention in the setting of severe LVOTO is still unknown, it is not surprising that these procedures are not universally accepted. Some centers have advocated fetal cardiac intervention only when it is felt to be a lifesaving procedure, such as in the setting of critical aortic stenosis with fetal hydrops.

In the year 2000, Kohl et al. (60) reported the world experience of fetal aortic balloon valvuloplasty. The small early clinical experience ($n = 12$) was quite poor, with only one “long-term” survivor. However, more encouraging data were recently reported by McElhinney et al. (61) from the Children’s Hospital of Boston and the Brigham and Women’s Hospital.

FIGURE 48.2. The spectrum of HLHS. **A:** Aortic atresia with mitral atresia is the most extreme form of HLHS. The LV is diminutive. The ascending aorta and arch are extremely hypoplastic, and flow is retrograde. Systemic output is ductal dependent. **B:** Aortic atresia with a patent MV. As in aortic atresia with mitral atresia, the ascending aorta and arch are hypoplastic and all systemic output is ductal dependent. There is inflow without outflow. As a result, the LV is hypertensive with hypertrophy and endocardial fibroelastosis. The left ventricular mass can be greater than normal and result in distortion of the inflow of the RV, resulting in tricuspid valve insufficiency. **C:** Aortic valve stenosis with a patent MV. The LV is hypoplastic, but antegrade flow through the aortic valve persists. The degree of ascending aortic and arch hypoplasia is less than that observed with aortic atresia. This end of the spectrum of HLHS blends smoothly into critical aortic stenosis, and decision making concerning suitability for two-ventricle repair can be challenging.

These data included 70 fetuses that underwent attempted aortic valvuloplasty for critical aortic stenosis with evolving HLHS between March 2000 and October 2008. There was a significant improvement in technical success (74%), and most procedures were performed with only percutaneous access (73%). Eight fetuses died related to the procedure (11% mortality). Although fetuses with a technically successful valvuloplasty had improved growth of the aortic valve and MV, intervention did not effectively promote left ventricular growth. Therefore, fetuses with a larger LV dimensions initially were more likely to sustain a biventricular circulation at the time of birth ($n = 15$). Based on these results, the authors were able to create a multivariable scoring system, excluding some fetuses that were not likely to respond to fetal intervention.

In utero therapy for HLHS with a severely restrictive or intact atrial septum has also been described. Successful decompression of the LA in utero may avoid severe hypoxemia at birth, and theoretically, may also reduce prenatal lung damage and improve otherwise-dismal outcomes (62–64). In a recent publication by Marshall et al. (65), technically successful atrial septoplasty was performed in 19 of 21 fetuses between October 2001 and November 2007, with two episodes of fetal death. The authors determined that creation of a larger defect was associated with better postnatal oxygenation; however, whether this confers a benefit to later survival is presently unknown.

ANATOMY

Various cardiac malformations characterized by variable degrees of underdevelopment of the left ventricular cavity are referred to as HLHS. Most broadly, HLHS includes any number of lesions with a dominant RV and systemic outflow obstruction that are not amenable to two-ventricle repair.

Underdevelopment of the Left Ventricle Outflow—Aorta Complex

Underdevelopment of the LV outflow—aorta complex, resulting in critical aortic valve stenosis or aortic valve atresia with an intact ventricular septum is the most recognized form of HLHS (66–68) (Fig. 48.2). A spectrum of abnormalities includes aortic valve atresia with mitral atresia, aortic valve atresia with a patent MV, and aortic stenosis with a patent MV. This final group with aortic stenosis and a patent MV blends smoothly into critical aortic stenosis. The general unifying etiologic explanation is that the growth and development of vascular structures are dependent to some degree on the relative quantity of blood flow during fetal development. As mentioned earlier, fetal echocardiographic observations have confirmed the progression from aortic stenosis to HLHS (41). In addition to these observations, supporting data for underdevelopment of the LV outflow—aortic complex as the inciting event are provided by the fact that with an intact ventricular septum, additional lesions, particularly MV hypoplasia, are always less severe than the degree of left ventricular outflow obstruction (69). The ascending aorta is hypoplastic; among patients undergoing surgery for HLHS, the mean aortic diameter was 3.3 ± 1.7 mm; 40% to 55% of patients had an ascending aorta of <2 mm (70,71). Blood flow in the arch is retrograde, and in aortic atresia, the ascending aorta serves only as a conduit for the retrograde flow of blood into the coronary arteries. A localized coarctation of the aorta is present in 80% of patients (9,72). Aortic stenosis with mitral stenosis makes up 23% to 26% of patients undergoing stage 1 palliation, whereas 36% to 46% have aortic atresia with mitral atresia and 20% to 29% have aortic atresia with a patent MV (73–75).

There are corresponding changes in the right side of the heart when there is left ventricular cavity hypoplasia. All right-sided cardiac structures are larger than normal including the right

atrium (RA), tricuspid valve, PA, and pulmonary valve. The RV is both enlarged and hypertrophied (8,9,66,68,72,76–78). The anatomy of the interventricular septum may be affected. The apex of the RV and apex of the hypoplastic LV remain in proximity and may be identified externally by the junction of the anterior descending coronary artery and the posterior descending coronary artery. The apical junction of the right and LV will not correspond to the apex of the ventricular mass, because the RV is folded around the hypoplastic LV (79). This may impact tricuspid valve anatomy and function of the RV (80,81).

Abnormalities of the tricuspid valve have been identified in up to 35% of patients with HLHS. In aortic atresia and a patent MV, the LV has inflow but not outflow; the result is significant hypertrophy of an LV that is larger than that with aortic and mitral atresia and in fact may have greater than normal mass (82). The larger ventricular mass may create distortion of the basilar inflow portion of the RV. The septal surface of the RV may appear to have deep apical sinuses or recesses, the result of the apex of the RV folding around the hypoplastic but hypertrophied LV. The subvalvar apparatus of the tricuspid valve may be more distorted than that found in aortic atresia with mitral atresia. The finding of tricuspid valve dysplasia is more common among patients with a patent MV, occurring in 50% in this subgroup (81,83). In addition to alterations of tricuspid valve function owing to left ventricular mass effect, other abnormalities of the tricuspid valve including identification of a bileaflet right atrioventricular valve are seen in 12% of patients whereas some degree of dysplasia of the tricuspid valve can be found in a third of patients. Volume overload of the single RV and resultant annular dilation may further contribute to the development of tricuspid insufficiency. An additional cause of tricuspid insufficiency may be right ventricular subendocardial ischemia occurring in the neonatal period either at the time of presentation or following stage 1 palliation. Evidence for this includes the observation of a bright appearance of the papillary muscles by echocardiography consistent with ischemia and elongated cords in association with the development of tricuspid insufficiency.

Patients with aortic atresia and a patent MV have been variably reported to be at increased risk for mortality after the Norwood procedure (84,85). Coronary artery abnormalities, specifically, fistulous connections between the epicardial coronaries and the LV, have been described in a subgroup of these patients (86). Endocardial fibroelastosis is frequently present and is thought to be the result of subendocardial ischemia as a consequence of suprasystemic left ventricular pressure during development (79,82,87,88). Within this subgroup, the potential for tricuspid valve insufficiency is increased and arrhythmias associated with endocardial fibroelastosis may also contribute to an increased mortality risk (89) (Fig. 48.3).

The least affected subgroup of HLHS is aortic stenosis with a patent MV. This form is thought to develop later during fetal development when the LV is more completely formed. This form blends smoothly into the spectrum of critical aortic stenosis. Decision making in patients with left ventricular outflow obstruction can be challenging. In the patient deemed to have an LV that is non-apex forming with a prohibitively hypoplastic MV, stage 1 palliation is generally chosen with a prognosis that may be favorable because the LV is able to contribute to cardiac output.

Forms of Hypoplastic Left Heart Syndrome with a Ventricular Septal Defect

There are various forms of HLHS that have in common a ventricular septal defect. This may include forms that otherwise resemble those described above except that they have a

ventricular septal defect that can be in any part of the septum. If these defects are small, the cause and development of HLHS may not be significantly different than in patients with HLHS and an intact septum. In this group, mitral atresia with a patent left ventricular outflow may be present and suggests that inflow obstruction may be the source of development of HLHS. Within this group are forms of double-outlet RV including double-outlet RV with mitral atresia without obstruction to aortic outflow and unbalanced atrioventricular septal defects. Although this latter group could arguably be placed outside HLHS, there are forms with undeniable hypoplasia of the LV.

Additional Anatomic Considerations

Abnormalities of systemic venous return are uncommon in the patient with HLHS. Persistent left superior vena cava (SVC) occurs in <5% (8,68). Abnormal pulmonary venous connection or drainage occurs in 5% of patients (90). Anomalous pulmonary venous connection may occur with an intact atrial septum or severely restrictive atrial septal defect. Frequently, there is a persistent levocardial vein that drains to the innominate vein (91). Rare cases of anomalous pulmonary venous connection directly to the RA also exist. Important coronary abnormalities are rare. Anomalous origin of either of the coronary arteries from the right PA has been described (92–95). Coronary–cameral fistulas have been observed in patients with aortic atresia and a patent MV. Additionally, patients with aortic atresia and a patent MV have been observed to have tortuous epicardial coronaries with increased medial thickness (96). Despite the origin of the coronary arteries from the small ascending aorta, the coronary ostia and proximal coronary artery calibers are normal (97).

Premature closure of the patent foramen ovale has been postulated as a cause of HLHS. Because the foramen ovale is the source of left ventricular preload in the fetus, one would expect that closure of the foramen ovale would starve the LV of preload and result in hypoplasia. Premature closure of the foramen ovale may also occur as a secondary event to LVOTO. As mentioned earlier, LVOTO will result in increased left atrial pressure, and increased left atrial pressure results in apposition of the fossa ovalis flap valve against the septum secundum. Premature closure or restriction of the foramen ovale might occur along with LVOTO and contribute to development of HLHS. Among patients with an intact ventricular septum, premature closure of the foramen ovale is associated with endocardial fibroelastosis and indicates that LVOTO with elevated left ventricular end-diastolic pressure and subendocardial ischemia was present (98). Among patients with premature foramenal closure and a ventricular septal defect, fibroelastosis is absent, indicating that premature closure was perhaps a primary event in the development of left ventricular hypoplasia.

PRESENTATION, DIAGNOSIS, AND ECHOCARDIOGRAPHIC IMAGING

Presentation

Today, many cases of HLHS are detected in the second trimester when a screening obstetric ultrasound shows an abnormal four-chamber view. Prenatal recognition of the disease allows timely parental counseling as well as optimal delivery planning. Delivery at a tertiary care facility is recommended, avoiding transport-related morbidities, and allows the mother to be in close proximity to her baby after birth (99). Most centers continue to advocate a vaginal delivery, although induction of labor may be deemed necessary if the mother lives a significant

FIGURE 48.3. A: A view from the diaphragmatic surface of a heart with aortic valve atresia and a patent mitral valve (MV). The LV cavity is hypoplastic, but the LV is hypertrophied. Septal anatomy is distorted, and the *triangle* marks the apex of the interventricular septum. The hypertrophied but hypoplastic LV can distort the basilar septum and result in tricuspid valve insufficiency. B: The septal surface of a heart with aortic atresia and a patent MV. The *triangle* indicates the apex of the LV and the *stars* indicate the boundaries of the interventricular septum (S). The deep apical sinuses are the result of the remaining RV wrapping around the hypoplastic but hypertrophied LV. C: A view from the diaphragmatic surface of a heart with aortic and mitral atresia. The LV can be identified but is extremely hypoplastic. There is less potential for distortion of the anatomy of the interventricular septum and the subvalvar apparatus of the tricuspid valve. E, endocardium; LA, left atrium; PV, pulmonary valve; RA, right atrium; RV, right ventricle; TV, tricuspid valve. (Reprinted from Smith A, Pozzi M, and Anderson RH. *The Morphology of Hypoplasia of the Left Heart*. In: Anderson RH, Pozzi M, and Hutchinson S. *Hypoplastic Left Heart Syndrome*, 2005, with kind permission of Springer Science and Business Media.)

distance from the tertiary care facility. Following delivery, prostaglandins are initiated to maintain ductal patency, and an echocardiogram is performed to confirm the diagnosis. If severe atrial septal restriction is suspected on the prenatal ultrasound, interventional cardiology and/or cardiothoracic surgery should be immediately available.

If the infant has not been prenatally diagnosed with HLHS, timing of presentation is somewhat variable and dependent on the degree of atrial-level restriction as well as ductal patency. During late fetal development, pulmonary vascular resistance (PVR) is high and pulmonary blood flow is limited to <10% of ventricular output. At birth, PVR decreases abruptly as a result of mechanical distention of the lung, increased oxygen tension, and increased shear stress. Although the greatest fall in PVR occurs shortly after birth, a clinically important decline in PVR continues within days of birth (100–102). Abu-Harb et al. (103) reviewed the time of presentation of obstructive left heart malformations. About one-quarter of their infants with HLHS became symptomatic within 24 hours of age. However, most infants had a “normal” neonatal examination, with development of symptoms after 48 hours of age, often

after hospital discharge. When the atrial septum is restrictive, the resultant left atrial hypertension leads to pulmonary congestion, resulting in early onset of tachypnea and cyanosis. When the atrial septum is widely patent, neonates with HLHS may initially appear normal, with adequate oxygenation and systemic perfusion. These infants have a more delayed presentation, with symptoms developing as the ductus arteriosus undergoes gradual spontaneous closure. With ductal regression, there is hypoperfusion of the systemic circulation with an associated augmentation of pulmonary blood flow. These infants usually present in the first week of life with feeding difficulties and respiratory distress, with rapid progression to congestive heart failure and shock.

Diagnosis

Physical examination in the neonate with a severely restrictive atrial septum will be most notable for intense cyanosis with respiratory distress. In contrast, the infant with a nonrestrictive atrial defect may appear relatively pink. The infant with

ductal closure is often lethargic and has respiratory distress, cool extremities, and pallor. Auscultation is generally benign, especially in comparison with a sometimes dramatic clinical picture. The second heart sound is single and loud, reflecting the absence of the aortic valve component and the associated PA hypertension. A third heart sound may be heard, especially in the presence of ventricular dysfunction. Murmurs are uncommon, although a soft systolic ejection murmur may be generated from increased flow across the pulmonary valve. A louder S1-coincident murmur may be heard if there is significant tricuspid regurgitation. The upper- and lower-extremity pulses are palpable and symmetric early but are reduced later as ductal closure ensues. Hepatomegaly is common and is generally seen in infants with a delayed presentation.

Chest radiographs are generally nondiagnostic but typically reflect the degree of atrial-level restriction. In the infant with a severely restrictive atrial septum, the heart size may be relatively normal; however, there is significant pulmonary edema. The radiographic findings may be misinterpreted as lung disease, leading to a delay in diagnosis. In contrast, if the atrial septum is nonrestrictive, there is pulmonary overcirculation with cardiomegaly. The right atrial border may be prominent with absence of the ascending aortic shadow.

The electrocardiogram does reflect the underlying pathology; however, it is nondiagnostic. Right-axis deviation and right ventricular hypertrophy are common but not distinctly different from the normal electrocardiogram of the neonate. Tall, peaked P waves, indicative of right atrial enlargement, have been reported in 30% to 40% of patients (7,8).

With diagnostic 2-D echocardiography readily available, the need for cardiac catheterization in an infant with HLHS has dramatically decreased. Cardiac catheterization is generally used as an adjunct tool when trying to better identify pulmonary venous anomalies, or possibly, coronary anomalies. Also, in the setting of a severely restrictive atrial septum, catheter intervention may be lifesaving.

Echocardiography

The diagnosis of HLHS can be readily made by 2-D echocardiography, with additional important hemodynamic information provided by Doppler echocardiography (90,104–111). The intracardiac anatomy and physiology should be investigated using a standard echocardiographic approach and should include multiple imaging views (long axis, short axis, apical four chamber, subcostal coronal, subcostal sagittal, suprasternal notch) with repeated Doppler assessments.

Parasternal Long-Axis View

The diagnosis of HLHS is often suspected immediately from a parasternal long-axis view with identification of a small, muscle-bound left ventricular chamber that does not extend to the cardiac apex (Fig. 48.4). The endocardial surface of the LV is often echobright, indicating areas of endocardial fibroelastosis. The LA is usually small but may be dilated in patients with a restrictive atrial septal defect. The ascending aorta can be well visualized from the long-axis view and is frequently small (2 to 3 mm in diameter); the aortic valve may or may not be patent. The MV is often imperforate, but when patent, the leaflets are thickened, with short or even absent papillary muscle chordal attachments. A ventricular septal defect is rare in the presence of aortic atresia, but color Doppler interrogation of the ventricular septum may show ventriculocoronary arterial connections. Although the significance of these abnormal coronary connections in HLHS is unclear, coronary artery sinusoidal connections have had prognostic implications in other forms of congenital heart disease (112,113).

FIGURE 48.4. Parasternal long-axis view in a patient with HLHS. The left ventricular chamber is small and muscle bound. The endocardial surface of the LV is echobright, consistent with endocardial fibroelastosis (arrow). Ao, aorta; LA, left atrium; RV, right ventricle.

Several measurements are available from the parasternal long-axis view, which can be helpful when trying to differentiate critical aortic stenosis from HLHS. A left ventricular cross-sectional area $<1.5 \text{ cm}^2$ is found in most infants with HLHS, as well as a left ventricular end-diastolic inflow dimension $<25 \text{ mm}$ (measured from the hinge point of the posterior mitral leaflet to the apex) and a mitral annulus diameter of $\leq 6 \text{ mm}$ (104,105).

Parasternal Short-Axis View

The parasternal short-axis view again allows assessment of left ventricular size and function (Fig. 48.5A). The MV papillary muscles are well visualized from this window and should be carefully examined. At the base of the heart, aortic valve size and anatomy can be well visualized. Doppler interrogation of the coronary arteries is often best assessed here. Bidirectional coronary flow is consistent with left ventriculocoronary arterial connections. Last, the main PA, pulmonary valve, and branch pulmonary arteries are all well seen from the short-axis view. Scanning more superiorly, the patent ductus arteriosus can be visualized as it sweeps to the descending aorta (Fig. 48.5B).

Apical Four-Chamber View

The apical four-chamber view is often critical for definitively evaluating left ventricular size and function. If a large portion of the cardiac apex is occupied by the RV (Fig. 48.6), it is unlikely that the LV can support the systemic circulation. The four-chamber view also provides an excellent window to see the entire mitral apparatus, including the subvalvar and supravalar areas. MV anatomy and annulus size should be reassessed, especially in cases of borderline left ventricular size.

Right ventricular function and tricuspid valve anatomy and competency are best assessed from the four-chamber view. Right ventricular systolic function may be depressed, especially in those neonates with ductal closure and acidosis. Tricuspid valve abnormalities are common and can include a bileaflet valve, tricuspid valve dysplasia/prolapse, and abnormal papillary muscle arrangements (81).

Subcostal Views

Atrial septal anatomy is best imaged from the subcostal views. Large atrial septal aneurysms billowing into the RA are

FIGURE 48.5. Parasternal short-axis views in a patient with HLHS. In (A) the right ventricle (RV) is enlarged with a smaller hypertrophied left ventricle (LV). Scanning more superiorly from a parasternal short-axis view (B), the larger main pulmonary artery (MPA) and patent ductus arteriosus (*arrow*) are seen connecting to the descending aorta. No brachiocephalic vessels are seen arising from the ductal arch, a key finding in differentiating the ductal arch from the true aortic arch. Ao aorta.

common (Fig. 48.7). Unusual attachments of septum primum can sometimes be seen, specifically anomalous attachment to the posterosuperior left atrial wall (Fig. 48.8). This anomalous attachment has been implicated in the pathogenesis of HLHS (48). If the atrial septal defect is small and restrictive, peak and mean Doppler gradients across the atrial septum should be obtained to estimate the degree of left atrial hypertension.

Pulmonary venous anatomy and drainage should also be interrogated from the subcostal window. It is important to identify connections of the pulmonary veins (anatomic attachment) as well as pulmonary venous drainage (the end point of pulmonary venous flow). The pulmonary veins may connect normally to the LA, but especially in cases of an intact atrial septum, there may be a levoatrial cardinal vein that originates directly from the LA and drains either all pulmonary veins (total) or some (partial) to a variable location. It is important to remember that this anomalous

venous structure can be stenotic, so the presence of the “decompressing” vein does not guarantee normal left atrial pressure (63). On the other hand, some or all of the pulmonary veins may not connect normally to the LA, but connect to a confluence behind the LA with anomalous drainage to a variable location. It is estimated that anomalous pulmonary venous anatomy and/or drainage occurs in about 5% to 10% of patients with HLHS.

Suprasternal Notch Views

The suprasternal notch provides an important window for evaluating aortic arch anatomy (Fig. 48.9). Although the ascending aorta can be imaged from many views, the transverse arch and descending thoracic aorta (DAo) are best seen from the suprasternal notch view. Coarctation of the aorta is common in patients with HLHS, and interruption of the aortic arch has also been reported. Doppler interrogation of the transverse arch should show retrograde systolic flow from the ductus; this finding indicates ductal-dependent systemic circulation and supports left ventricular inadequacy for biventricular repair (Fig. 48.10). The suprasternal notch views also provide images of the proximal pulmonary arteries and the ductus arteriosus. In the patient with a later presentation, the ductus may be restrictive; Doppler interrogation of the pressure gradient from PA to aorta should be quantified and follow-up studies performed when prostaglandin therapy is initiated. Pulmonary venous connection and drainage should be reassessed from this window. A persistent left SVC or levoatrial cardinal vein can be well imaged to the left of the descending aorta from the suprasternal notch view.

FIGURE 48.6. Apical four-chamber view in a patient with HLHS. The left atrium (LA) and left ventricle (LV) are much smaller than the right atrium (RA) and right ventricle (RV). The RV clearly occupies the cardiac apex.

PHYSIOLOGY, MONITORING, AND STABILIZATION

Parallel Circulation

The patient with HLHS faces similar physiologic challenges before, during, and after stage 1 palliation. The superimposition of inefficient parallel circulation, cyanosis, myocardial dysfunction, and autonomic and inflammatory

FIGURE 48.7. Subcostal sagittal view in a patient with HLHS. The atrial septum is aneurysmal (*arrows*), bowing into the RA. Color Doppler imaging identifies the superiorly positioned atrial shunt with the jet directed into the superior vena cava (SVC). Aliasing of the color Doppler flow signal across the atrial septum is consistent with a restrictive defect and can result in left atrial hypertension. LA, left atrium.

responses to stress and surgery result in high likelihood of critical impairment of oxygen delivery with subsequent organ dysfunction or death. Thus, facility with the principles of hemodynamics and oxygen supply/demand economy is a prerequisite for rational perioperative treatment of first-stage palliation patients.

Maintenance of adequate organ substrate delivery, oxygen, is necessary to reverse or prevent ischemic injury, which can result in multisystem organ dysfunction, prolonged morbidity, and mortality (114–120). Interventions targeting early treatment of inadequate whole-body or regional oxygen supply/demand relationships (shock) have improved outcome in critical illness; therefore detection of inadequate oxygen delivery is important for preventive or therapeutic interventions (114,115,121–126).

FIGURE 48.8. Subcostal coronal view in a patient with HLHS. The left atrium (LA) is small with leftward deviation of septum primum and anomalous attachment of the septum to the posterolateral left atrial wall (*arrow*). RA, right atrium.

FIGURE 48.9. Suprasternal long-axis view from a patient with HLHS and aortic atresia. The ascending aorta (*arrows*) is markedly hypoplastic, measuring 2 mm, with a fair-sized transverse arch connecting to the descending thoracic aorta (DAo). Brachiocephalic vessels are seen arising from the transverse aorta, identifying this structure as the true aortic arch.

Cardiovascular Reflexes and Physiology of Shock

Efficient delivery of oxygen to meet metabolic demand occurs through regional and global circulatory controls. Global cardiac output is affected by preload, afterload, rate, rhythm, contractility, and the presence of aortopulmonary shunts. Regional resistance is determined by the interaction of neurohumoral factors related to inflammation and the sympathetic nervous system, and local factors related to autoregulation. The total systemic vascular resistance (SVR) is thus determined by the net effect of regional resistances. Oxygen delivery ($\dot{V}O_2$) is systemic cardiac output (Q_s) multiplied by arterial oxygen content (CaO_2), which is determined by the hemoglobin (Hb) concentration, oxygen saturation (SaO_2), and oxygen tension (PaO_2):

$$CaO_2 = 1.34 \times Hb \times SaO_2 + 0.003 \times PaO_2 \quad (1)$$

$$\dot{V}O_2 = CaO_2 \times Q_s \quad (2)$$

The sympathetic stress response as described with hypovolemic-septic shock (127–129) is activated in all shock states to redistribute blood flow to the brain and heart (130–132). The distribution of cardiac output can be significantly altered by stress responses, with the mesenteric and splanchnic circulations being at risk for silent ischemia during compensated shock (133–136). Circulatory reflexes to hemorrhage or hypotension will increase baroreflex gain to raise contractility, heart rate, and SVR, and decrease venous capacitance (137–140). These responses may be immediately protective in the face of hemorrhagic shock but often impair systemic flow in the face of myocardial dysfunction (141,142). These responses are also activated by cold stress, pain, and anxiety, and thus are not specific to hypovolemia (143–146). The vigor of the vascular component of the stress response may actually cause blood pressure to be elevated in the face of low cardiac output in the stressed neonate or child (147). The predominant profile of shock in pediatric patients is low cardiac output and very high SVR (148).

FIGURE 48.10. Pulsed Doppler examination from the suprasternal notch in a patient with HLHS. With the sample volume positioned in the transverse arch, retrograde systolic flow (arrows) from the patent ductus arteriosus into the aorta is identified, consistent with ductal-dependent systemic circulation.

The organs in the splanchnic circulation are the first to suffer ischemic injury because sympathetic outflow and innervation is rich in these regions (135,149–152) and because of the selective effects of angiotensin (153,154). Ischemic organ damage may occur even in the presence of normal global oxygen economy if regional vascular resistance is sufficiently elevated (133,134,155–157). There now exists compelling evidence that splanchnic/mesenteric ischemia is a frequent common pathway for multisystem organ dysfunction and death (158–161), and regional cellular oxygen deficit is underrecognized, underdiagnosed, and undertreated (162). Strategies targeting earlier detection and treatment of shock could improve outcome, with greater impact in populations with higher baseline mortality risk (163). The mortality risk in the neonate with HLHS, even with contemporary management, is high enough to justify the additional complexity of oxygen-delivery goal-directed approaches to prevention, detection, and management of shock states (164).

Oxygen Flux in Single-Ventricle Parallel Circulation

With univentricular parallel anatomy, both the pulmonary circulation and the systemic circulation are fed by arterial blood that is only partially saturated with oxygen. Because arterial saturation (SaO_2) is reduced by mixing, and because Q_s may be reduced by various factors, a reduction in $\dot{\text{D}}\text{O}_2$ is typically encountered in patients with HLHS, with a resulting higher risk of cellular hypoxia as a major physiologic vulnerability. Applying the Fick principle (equality of systemic oxygen consumption and pulmonary oxygen uptake) to the patient with HLHS yields the following relationships between oxygen consumption ($\dot{\text{V}}\text{O}_2$), pulmonary blood flow (Q_p), systemic blood flow (Q_s), SaO_2 , systemic venous saturation (SvO_2), and pulmonary venous saturation (SpvO_2), which allows estimation of the pulmonary-to-systemic flow ratio (Q_p/Q_s) in the parallel circulation:

$$\dot{\text{V}}\text{O}_2 = \text{Q}_s \times (\text{SaO}_2 - \text{SvO}_2) \quad (3)$$

$$\dot{\text{V}}\text{O}_2 = \text{Q}_p \times (\text{SpvO}_2 - \text{SaO}_2) \quad (4)$$

$$\frac{\text{Q}_p}{\text{Q}_s} = \frac{(\text{SaO}_2 - \text{SvO}_2)}{(\text{SpvO}_2 - \text{SaO}_2)} \quad (5)$$

Optimal systemic oxygen delivery in univentricular models occurs at the lowest total cardiac output when Q_p/Q_s is close to 1 (165). This economy occurs with the total ventricular output (Q_t) being twice the normal output of an in-series systemic ventricle, to yield normal values for both Q_s and Q_p . With a Q_p/Q_s of 1 and an arterial–venous saturation difference ($\text{SaO}_2 - \text{SvO}_2$) of 25%, oxygen uptake/consumption equilibrium will occur when the pulmonary capillary–arterial saturation difference ($\text{SpvO}_2 - \text{SaO}_2$) also equals 25%, resulting in an SaO_2 of 75% and an SvO_2 of 50%, assuming that pulmonary venous blood is fully saturated. If SaO_2 is >75%, a higher Q_p is necessary to maintain the same pulmonary O_2 uptake; conversely if Q_p falls, SaO_2 will also fall. If the SaO_2 is low, then a higher Q_s is necessary to maintain systemic O_2 uptake; if Q_s falls, then SaO_2 also falls. Changes in SaO_2 result in opposite effects on pulmonary and systemic oxygen economy. Conversely, since a tradeoff of Q_s and Q_p will exist for any Q_t , increases in SaO_2 that are not a result of increased Q_t will be offset by a reduction in Q_s . Referring to the first three examples in Table 48.1, moderately large changes in Q_p/Q_s with constant Q_t (assuming a hemoglobin of 15 g/dL, SpvO_2 of 100%, and indexed $\dot{\text{V}}\text{O}_2$ of 160 mL/m²/min) show a range of SaO_2 from 63% to 82% but a narrower range of SvO_2 for 44% to 50%. As a result, moderate alterations in Q_p/Q_s balance will have minimal effect on $\dot{\text{D}}\text{O}_2$; more effectively, alterable determinants of $\dot{\text{D}}\text{O}_2$ include hemoglobin and Q_t . Oxygen economy at higher or lower Q_p/Q_s and varying Q_t is illustrated in Table 48.1.

In single-ventricle parallel circulation, solution of the Fick equation shows that the SaO_2 depends on both systemic and pulmonary flow and saturation:

$$\text{SaO}_2 = \frac{(\text{Q}_p \times \text{SpvO}_2 + \text{Q}_s \times \text{SvO}_2)}{(\text{Q}_p + \text{Q}_s)} \quad (6)$$

Changes in Q_t , over a range of Q_p/Q_s , have a more profound effect on SvO_2 . Thus matching of $\dot{\text{D}}\text{O}_2$ to changes in $\dot{\text{V}}\text{O}_2$ are more effective via interventions in total cardiac output or hemoglobin concentration than by precise manipulation of Q_p/Q_s balance.

An important limitation in circulatory reserve resulting from this complex relationship is that increases in systemic oxygen consumption cannot be buffered by increased extraction (166). This limitation is best clarified by comparison of

TABLE 48.1 Effect of Varying Qp/Qs and Qt on Arteriovenous Saturations in Parallel Circulation

Qp/Qs	SvO ₂ (%)	Spv-aO ₂ (%)	Qp	Sa-vO ₂ (%)	Qs	Qt	SaO ₂ (%)
1.0	50	25	3.2	25	3.2	6.4	75

Assumptions: hemoglobin 15 g/dL, oxygen consumption 160 mL/m², pulmonary venous saturation of 100%.

the oxygen cascade diagram between in-series and parallel circulation (Fig. 48.11).

In a patient with *normal in-series circulation*, at constant cardiac output, increased VO₂ will reduce SvO₂, but pulmonary oxygen uptake will increase to match. In the critically ill patient, tissue oxygen utilization will usually continue until the SvO₂ falls to <50%; thus, a doubling of VO₂ can be met without an increase in cardiac output. Since normal lungs can fully oxygenate fully desaturated systemic venous blood, the resulting SaO₂ is unchanged, $\dot{D}O_2$ is maintained, and the increased VO₂ can be met by increased extraction alone. Similarly, cellular oxygen utilization can be maintained during a reduction in cardiac output and $\dot{D}O_2$ by increased extraction.

In a patient with *univentricular parallel circulation*, increased oxygen extraction (either because of increased VO₂ or decreased $\dot{D}O_2$) will reduce SvO₂ and SaO₂. The result is that conditions that increase oxygen extraction will also decrease oxygen delivery through a reduction in SaO₂. For any given Qp/Qs, the increased tissue oxygen demand can be met only by increased cardiac output. For any given fall in cardiac output, $\dot{D}O_2$ and SvO₂ will be disproportionately reduced, because SaO₂ will also fall. Thus, changes in oxygen supply and demand are interdependent and destabilizing in the patient with parallel univentricular physiology.

Monitoring the Parallel Circulation

The first successful approaches to monitoring and managing the patient with HLHS emphasized the central importance of SaO₂ in detecting and guiding treatment of unbalanced

pulmonary-to-systemic blood flow ratio and total cardiac output (167). Generalization of this approach was based on circulatory models that assumed either a constant arteriovenous oxygen difference (of typically 25%) or a constant mixed SvO₂ (of typically 50%). In either model, an SaO₂ of 75% would then result from mixing equal parts of systemic venous and (fully saturated) pulmonary venous blood; deviations of SaO₂ from 75% in these models would result from, and be diagnostic of, deviations of Qp/Qs from 1. These approaches also assumed adequate total cardiac output to meet oxygen delivery needs if Qp/Qs is optimized. Under these conditions, systemic oxygen delivery generally increases as SaO₂ approaches 75% to 80% and falls at higher saturation owing to increasing Qp/Qs imbalance. However, in the perioperative period, total cardiac output and metabolic demand may frequently be mismatched as a result of the inherent instability of parallel circulation as described above, and variability of Qp/Qs, Qt, and VO₂ (168–170). Inspection of Table 48.1 reveals that assertions about the Qp/Qs from a single measured SaO₂ value are unreliable unless either SvO₂, or VO₂ and Qt, are known. A target SaO₂ of 75% can result from a range of Qp/Qs and SvO₂ conditions, which may include inadequate systemic flow if Qt or VO₂ is variable. In a circulatory model that allows for variation in both total cardiac output and Qp/Qs, a wide range of tissue/venous saturation can result at any given SaO₂, shown graphically in Figure 48.12. The resulting domain of SvO₂ shows that severely impaired systemic oxygen delivery can occur with SaO₂ closely maintained in the target 75% to 80% range.

A report of increased stability with the use of inspired carbon dioxide (CO₂) (167) led to the wide adoption of manipulation of medical gases to control PVR and Qp/Qs. Theoretic

FIGURE 48.11. Oxygen flux in series and parallel circulations. In contrast to series circulation, in a parallel circulation, arterial blood derives from a mixture of systemic venous and pulmonary venous return and is divided into systemic and pulmonary flow according to relative resistances.

FIGURE 48.12. The range of SvO₂ at any given SaO₂ is shown in a model with variable total cardiac output and bounded by Qp/Qs as low as 0.5 and as high as two. For any SaO₂, a range of SvO₂ is possible. The slope of the SaO₂–SvO₂ relationship, as total cardiac output changes, is determined by the Qp/Qs ratio. (Reprinted from Hoffman GM and Stuth EA. Hypoplastic left heart syndrome. In: Lake CL, Booker PD, eds. *Pediatric Cardiac Anesthesia*. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2005, with kind permission of Lippincott Williams & Wilkins.)

and experimental models showed that inspired CO₂ increased PVR, and moderately decreased SVR, and would increase systemic oxygen delivery (171,172). As part of this approach, the SaO₂ was used as a key indicator to detect pulmonary overcirculation, which would result in a higher SaO₂ as Qp/Qs rose. However, this would be true only if the systemic arteriovenous difference did not increase, which would occur only if the increase in Qp resulted from increased Qt at constant Qs. The primary concern over preventing a runaway spiral of increased Qp/Qs led to the use of low or even subatmospheric fraction of inspired oxygen (fiO₂) in further attempts to raise the PVR (173,174).

Preoperatively, these approaches may be partially effective in limiting pulmonary overcirculation, but only hypercapnia increases systemic oxygen delivery (175). In contrast, a synthetic shunt placed at the time of initial palliation imposes a large fixed resistor into the total pulmonary resistance, which is of similar magnitude to the SVR. This arrangement reduces the efficacy of PVR manipulations on hemodynamics (176,177). Reduction of fiO₂ may cause the resulting alveolar oxygen tension to be inadequate to fully oxygenate the pulmonary capillary blood, an effect that may be common at fiO₂ < 0.3 (178). Thus, reduction in SaO₂ by intentionally limiting fiO₂ may result solely from pulmonary capillary desaturation rather than reductions in Qp. This will reduce oxygen uptake across the lung, waste pulmonary blood flow, and reduce oxygen available for tissue utilization. Unless SpvO₂ is measured or fiO₂ is high enough to make pulmonary capillary desaturation unlikely, the calculated Qp/Qs at low fiO₂ may be falsely low because of SpvO₂ < 95%. Because of variability in both SpvO₂ and the arteriovenous saturation difference, the SaO₂ does not reliably characterize the parallel circulation.

The importance of both SVR and PVR in determining Qp/Qs was emphasized in modeling studies (176). In these studies, the Qp/Qs range could be restricted by placement of a resistive shunt, and the importance of shunt size was emphasized. These models also demonstrated that the combination of low total cardiac output and high Qp/Qs severely impaired systemic oxygen delivery. Even in the presence of a resistive shunt in the pulmonary circulation, control of elevated SVR was more effective than increases in PVR to optimize systemic oxygen delivery.

Without knowledge of SvO₂ or tissue oxygenation, the effect of any intervention on systemic oxygenation remains difficult to assess. Not surprisingly, perioperative management based primarily on optimization of SaO₂ is associated with an early mortality of >20%. With this approach, cardiovascular collapse and mortality typically result from an acute hemodynamic event that occurs unexpectedly in an apparently stable postoperative hemodynamic setting (73,179,180). Because sympathetic vasomotor tone and thus SVR increase as systemic flow falls, changes in Qp/Qs can occur rapidly, resulting in deterioration of systemic oxygen delivery in a self-reinforcing cycle. Precisely, because of the Qp/Qs tradeoff, these changes are usually not readily apparent with arterial pressure or oxygen saturation monitoring as demonstrated in Figure 48.13. This above analysis provides an explanation for the profound circulatory derangements that are possible despite having SaO₂ in the typical target range. These theoretical and actual limitations have led to the development of management strategies aided by SvO₂ measurement to more closely assess Qp/Qs, adequacy of oxygen delivery, and whole-body oxygen economy.

It is not possible to obtain a true mixed venous blood sample in the patient with HLHS, but approximate measures of the mixed venous oxyhemoglobin saturation can be obtained from blood withdrawn from the SVC. Placement of a catheter in the SVC primarily to allow sampling of quasi-mixed venous blood is more likely to be helpful in guiding perioperative management. Small (4 Fr) oximetric catheters placed in the SVC just prior to weaning from bypass in neonates undergoing Norwood-type repairs allow continuous readout of SVC saturation. Used as an approximation of SvO₂, monitoring SVC saturation allows timely hemodynamic intervention to avoid anaerobic metabolism, which has an apparent SVO₂ threshold near 30% in this population (181). The use of continuous SvO₂ has greatly reduced the perioperative occurrence of sudden unexpected circulatory collapse (73,179,182). However, this measure is available only rarely preoperatively, and for a limited time postoperatively.

Near-infrared spectroscopy (NIRS) monitoring of tissue oxygen status has been used as an adjunct to perioperative management. NIRS devices with a 4-cm source–detector distance can measure the average oxyhemoglobin saturation (rSO₂) in tissue about 2 to 3 cm below the skin, and has

FIGURE 48.13. A Multichannel recording of early ICU course after Norwood procedure without phenoxybenzamine, showing severe deterioration in systemic oxygen delivery without significant changes in other conventionally monitored parameters. Continuously recorded data are from a single neonate arriving in the ICU after the Norwood procedure, performed without phenoxybenzamine. A life-threatening hemodynamic deterioration is clearly shown with SvO₂ monitoring despite SaO₂ in the 75% to 80% range. An initial deterioration in SvO₂ (arrow a) was partially corrected with additional analgesia (arrow b) but did not prevent a subsequent critical deterioration in systemic oxygen delivery (arrow e), which was effectively treated with a combination of additional analgesia/anesthesia and increased inotropic and vasodilator infusions. Conventional parameters (arterial blood pressure and SaO₂) show only subtle changes that provide neither an early warning of the critical situation nor feedback about the effectiveness of corrective measures. ART, mean arterial blood pressure; FiO₂, fraction of inspired oxygen; PetCO₂, end-tidal carbon dioxide; SaO₂, arterial saturation; SvO₂, systemic venous saturation. (Reprinted from Hoffman GM and Stuth EA. Hypoplastic left heart syndrome. In: Lake CL, Booker PD, eds. *Pediatric Cardiac Anesthesia*, 4th ed. 2005, with kind permission of Lippincott Williams & Wilkins.)

been used to monitor oxyhemoglobin saturation in a range of organs including brain, muscle, kidney, and gut (183,184). The probes are most commonly placed on the forehead to monitor cerebral oxygenation, and on the T10-L2 flank region to monitor somatic saturation, as an attempt to capture circulations under intense autoregulatory (cerebral) and autonomic (renal or splanchnic somatic) control. Combining NIRS rSO₂ from these two regional circulations in a linear model allows better approximation of SvO₂ and thus provides information about both regional and global oxygen economies as a noninvasive SvO₂ surrogate (185–188) (Fig. 48.14). Given the instability of oxygen supply/demand relationships, and the inadequacy of assessment based on arterial blood pressure and SaO₂ monitoring, improved outcome requires early detection and treatment of deficiencies in oxygen economy. Direct or surrogate measurement of SvO₂ permits continuous assessment of adequacy of systemic oxygen delivery in the most vulnerable postoperative period. Low total cardiac output and unbalanced Qp/Qs can be differentiated physiologically, interventions can be rationally based, and patient responses can be quantified and trended. We have found continuous SvO₂ monitoring to be the single most important factor in improving survival after stage 1 palliation (73), and our current approach relies on noninvasive pre- and postoperative detection of circulatory deterioration with NIRS (189–191).

Preoperative Preparation

Prostaglandin E₁

Maintaining ductal patency in a neonate with HLHS is vital in the preoperative management. Although ductal closure is rarely immediate, nearly all infants will have physiologic closure of the ductus arteriosus by the fourth day of life; 20% of infants will demonstrate functional ductal closure during the first day of life, and >80% of infants demonstrate ductal closure during the second day of life. For this reason, prostaglandin E₁ (PGE₁) therapy should be initiated immediately when HLHS is diagnosed or suspected (192–194). The patient's physiologic state often directs initial PGE₁ dosing. For patients who present in shock with suspected ductal closure or a restrictive duct, initial dosing will range from 0.05 to 0.1 µg/kg/min. Once ductal patency is ensured, the infusion rate can be decreased to an effective dose as low as 0.01 µg/kg/min (195).

Ductal patency with the lowest effective PGE₁ dose minimizes the most common dose-dependent side effects of PGE₁: hypotension prompting volume resuscitation and respiratory depression requiring mechanical support (195–197). Initiation of intravenous caffeine with a loading dose of 20 mg/kg followed by a maintenance dose of

FIGURE 48.14. Actual SvO₂ and values predicted from two-site NIRS model. A neonate after the Norwood procedure performed with phenoxybenzamine has SVC SvO₂ monitoring and NIRS probes over frontal cerebral and T10-L2 somatic (renal) sites. A linear model of NIRS data closely tracks actual SvO₂ data. (Model SvO₂ = $0.45 \times rSO_2$ cerebral + $0.45 \times rSO_2$ somatic.) CI, confidence interval; rSO₂, regional oxygen saturation; SvO₂, systemic venous oxygen saturation. (Adapted from Hoffman GM, Stuth EA, Berens RJ, et al. Two-site near-infrared transcutaneous oximetry as a non-invasive indicator of mixed venous oxygen saturation in cardiac neonates. *Anesthesiology* 2003;97:A1393)

5 to 10 mg/kg/day has been effective in reducing the need for mechanical ventilation preoperatively. This approach is based on a study in neonates receiving low-dose PGE₁ who were simultaneously being treated with aminophylline or placebo. Patients who received aminophylline had a decreased incidence of apnea and did not require intubation when compared with the placebo group of whom 35% required intubation (198).

Respiratory Support and Inspired Gases

In the preoperative patient without anatomic limitation to pulmonary blood flow, mechanical ventilation and medical gas manipulation of pulmonary arteriolar resistance are sometimes necessary and beneficial. Controlled positive-pressure ventilation with care taken to avoid hyperventilation can limit pulmonary blood flow. Additionally, the use of positive end-expiratory pressure (PEEP) allows delivery of lung volumes that exceed functional residual capacity and subsequently results in compression of pulmonary vasculature with a resultant increase in PVR.

Medical gas management can be used to increase PVR and reduce Qp/Qs. Inspired CO₂ as a means to limit pulmonary blood flow and treat instability first became apparent in the early 1990s (167). Subsequent animal models have confirmed the effectiveness of inspired CO₂ on lowering the pH and raising PVR while successfully increasing systemic flow (171,172,199). Animal models have similarly demonstrated the effectiveness of subatmospheric FiO₂ in increasing PVR (172,199). Clinical experience supports the use of hypoxia as a means to attenuate an elevated Qp/Qs (173,200). Hypoxic gas mixtures are achieved through blending nitrogen and oxygen to achieve inspired subatmospheric FiO₂ of 0.14 to 0.20. The use of inspired gases in humans has been best studied in an acute model by Tabbutt et al. (175). Preoperative neonates with HLHS who were anesthetized and under neuromuscular blockade were ventilated with a hypoxic gas mixture (FiO₂ of 0.17) and with supplemental CO₂ (fICO₂ of 0.03). Although both strategies were successful in acutely

reducing SaO₂ and Qp/Qs, only hypercarbia improved systemic oxygen delivery (175). Furthermore, whereas hypercarbia improved cerebral oxygenation, hypoxia provided no benefit to cerebral saturation (201).

In general, excessive supplemental oxygen, a potent pulmonary vasodilator, is avoided in the preoperative management of HLHS, although patients with respiratory distress syndrome, pneumonia, atelectasis, or other primary lung pathology might benefit from the use of supplemental oxygen for severe hypoxia. Patients with restrictive atrial communication also necessitate supplemental oxygen administration. For these patients, controlled ventilation is instituted with supplemental oxygen, with titration based upon both arterial and regional or venous oxygen measures by NIRS, which allows the decoding of the complex interactions of FiO₂ and pCO₂ on pulmonary blood flow, systemic blood flow, and total oxygen delivery. In patients who have severely restrictive or absent atrial septal defect, supplemental oxygen and other medical therapies are ineffective in treating the severe arterial desaturation, prompting emergency intervention with balloon atrial septostomy, atrial septal balloon dilation and/or stent, surgical septectomy, or immediate stage 1 palliation.

Vasoactive Medications

The need for preoperative inotropic support is variable and directed by clinical presentation and echocardiographic features. More recently, we have used noninvasive but continuous monitoring with NIRS to facilitate a less-invasive preoperative stabilization strategy (189). Patients who present in cardiogenic shock most commonly benefit from inotropic support as do patients with significantly reduced right ventricular function. On whole, inotropic catecholamines have been shown to reduce or have little effect on Qp/Qs in an animal model (172), but dose escalation may result in an undesired increase in SVR that subsequently raises Qp/Qs. For those patients in whom Qp/Qs is elevated and systemic perfusion is compromised, inodilator therapy with milrinone, a phosphodiesterase inhibitor, might be warranted. Milrinone, however, also has been shown to reduce PVR and again carries the undesired risk of increasing Qp/Qs. Furthermore, milrinone could result in significant hypotension in patients already at risk for decreased perfusion secondary to aortopulmonary runoff. Strategic monitoring and thoughtful assessment of these patients will be directed at these concerns.

Other Adjunctive Therapies

The hypoxic patient with inefficient single-ventricle physiology benefits from increased oxygen carrying capacity. Increasing the hematocrit to 50% will benefit the patient with limited Qp or Qt. Other means to improve systemic perfusion include therapies that attenuate sympathetic vascular tone. Specifically, for the stressed neonate with increased SVR, low-dose morphine can be used to reduce agitation and work of breathing and to improve systemic oxygen balance (189). Parenteral nutrition is provided with volume administration that is consistent with gestational age, birth weight, and postnatal age. For the term infant who is >2,500 g, our recommendations for fluid requirements during the first day of life are 70 to 80 mL/kg/day with escalation to 100 mL/kg/day on day of life three and then, 120 to 140 mL/kg/day for infants 4 days of age and older. The preterm infant requires more fluid due to higher transdermal insensible losses at a lower weight. Diuretic therapy is reserved for those patients who demonstrate respiratory insufficiency from increased interstitial lung edema related to either pulmonary overcirculation or restrictive pulmonary venous return.

Any of the proposed preoperative management strategies can be used in isolation or combination to balance

FIGURE 48.15. Stage 1 palliation of HLHS. **A:** Stage 1 palliation (Norwood procedure) using a modified BT shunt for provision of pulmonary blood flow. The shunt originates from the innominate artery and inserts into the central PA. **B:** Stage 1 palliation using an RV-to-PA conduit (Sano modification) for provision of pulmonary blood flow. A larger 5- or 6-mm graft is placed between the RV and the central PA. **C:** Stage 1 palliation using a hybrid approach. Pulmonary blood flow is restricted with branch PA bands, and the ductal patency is maintained by placement of a stent. A stent is placed to create a nonrestrictive atrial septal defect.

pulmonary-to-systemic flow, optimize systemic perfusion, and preserve organ function. However, each should be embarked on only with sufficient monitoring as they can pose potential risks to the neonate awaiting staged palliation for HLHS.

STAGED PALLIATION

With inadequate anatomic substrate for a two-ventricle repair, surgical approaches must address the relatively high and variable PVR in the neonate as well as the subsequent reduction in PVR that allows an eventual more stable and economical in-series circulation. Recognition of such physiologic necessities drove the development of numerous surgical approaches (202,203). Permutations of a staged surgical pathway that was successfully championed by Norwood et al. (204,205) are now widely used. The staged approach ultimately leads the patient on a pathway to a single-ventricle in-series circulation, usually culminating in a Fontan operation with the final result similar to patients with tricuspid atresia and hypoplastic right heart syndrome (206). Most commonly, stage 1 palliation consists of reconstruction of the aortic arch into the right ventricular outflow, separation of branch pulmonary arteries from the RV, and creation of a restrictive source of pulmonary blood flow from a systemic artery or directly from the single ventricle (205,207). Stage 2 palliation unloads the single ventricle by replacing the systemic-to-pulmonary shunt with a superior cavopulmonary anastomosis (208). The staged pathway is completed by modifications of a Fontan connection from the inferior vena cava (IVC) to the pulmonary arteries, with or without fenestration (205,209,210).

Stage 1 Palliation

Surgical Approaches

The goals of stage 1 palliation include relief of ductal-dependent systemic flow, provision of unrestricted coronary artery flow, creation of a nonrestrictive atrial septal defect

to prevent pulmonary venous hypertension, and provision of a reliable but restricted source of pulmonary blood flow (Fig. 48.15). Surgical strategies are varied, and the introduction of the hybrid procedure revisits early strategies of Litwin and Van Praagh to accomplish the goals of stage 1 palliation without the use of cardiopulmonary bypass (CPB) (211–214).

Stage 1 palliation using either a modified Blalock-Taussig (MBTT) shunt or RV-to-PA conduit (Sano modification) is accomplished using CPB, deep hypothermia, and altered perfusion—either circulatory arrest or regional perfusion. A connection is created between the smaller ascending aorta and the pulmonary root for provision of coronary blood flow. Restructuring of the heart's outflow via the pulmonary root is accomplished along with relief of coarctation and arch hypoplasia. Variations in surgical techniques include resection of ductal tissue or coarctectomy as opposed to patching of the region of ductal insertion. The aim of stage 1 palliation is to create a stable anatomy that permits growth and maturation of the pulmonary vasculature so that it can accommodate subsequent single-ventricle palliation. It is important that successful surgical strategies have a low incidence of recurrent or residual lesions because these are a source of interstage mortality and can limit suitability for single-ventricle palliation. Development of a restrictive atrial septal defect rarely complicates the interstage course (215). The observation that smaller ascending aortic size and presence of aortic atresia are risk factors for mortality is an indication that coronary insufficiency is a cause of death following stage 1 palliation, and strategies that target creation of a large ascending aorta-to-pulmonary root anastomosis are likely to result in improved outcome (216–219). Arch reconstruction strategies that include coarctectomy appear to have a lower incidence of late arch obstruction (70,216).

A modification of the systemic-to-pulmonary artery shunt developed by Blalock, Thomas, and Taussig has historically been the source of pulmonary blood flow following stage 1 palliation (220). Typically, this shunt originates from the innominate artery or the aorta. Both the diameter and length of this shunt are relevant to determining its flow-resistive characteristics (176). The resulting anatomy ideally provides

enough resistance to pulmonary blood flow to avoid destabilization from excessive pulmonary blood flow in the postoperative period. Physiologic limitations result from the inherent Qp/Qs mismatch of the parallel circulation and diastolic aortic runoff to the pulmonary circulation with risk of aortocoronary flow impairment (221,222). Additionally, competition between cerebral and pulmonary circulations for blood flow is possible if the shunt originates from the innominate artery (183). Furthermore, the systemic-to-pulmonary artery shunt is susceptible to occlusion from thrombosis or thromboembolism (215,223).

Recently, the right ventricle–pulmonary artery (RVPA) conduit as a source of pulmonary blood flow as part of the Norwood procedure was reintroduced (224,225). In this modification, pulmonary blood flow is supplied by conduit, generally a Gore-Tex tube graft, from the RV to the PA (224). A theoretical advantage of the RVPA shunt is the elimination of diastolic runoff and increased diastolic pressure with improved coronary perfusion pressure (226–233). Potential disadvantages include a negative effect on right ventricular function and ventricular arrhythmias due to the ventriculotomy, impaired growth of the pulmonary arteries, and the need for an earlier stage II procedure (230,234–236). Single-institution series comparing outcome of the Blalock-Thomas-Taussig shunt and RVPA conduit provided conflicting results (226–228,231,233,234,237–240). The Single-Ventricle Reconstruction Trial was a multi-institutional randomized trial of 549 patients comparing the MBTT shunt and the RVPA conduit. Among patients who had stage 1 palliation, transplantation-free survival 12 months after randomization was higher with the RVPA conduit than with the MBTT shunt (74% vs. 64%, $p = 0.01$) (Fig. 48.16). After 12 months, there was no survival advantage to the RVPA conduit, and the RVPA shunt group had more unintended interventions ($p = 0.003$) and complications ($p = 0.002$) (241).

Branch PA banding has been reported as a successful approach to reduce excessive pulmonary blood flow and permit a sufficient decrease in PVR to allow later stage 1 repair

or to reduce mortality while awaiting a donor heart (242). Use of this approach has also been reported in the rare neonate who cannot be stabilized by medical interventions because of excessive pulmonary blood flow (243). The hybrid approach uses surgical branch PA banding combined with transcatheter ductal stenting (211–213,244). Intervention to provide a reliable atrial septal communication is also necessary and may include a balloon septostomy and/or stent placement within the atrial septum (245). The result is anatomy that achieves the goals of stage 1 palliation without the need of CPB and deep hypothermia. The second-stage procedure combines aortic arch reconstruction and a superior cavopulmonary connection (191,212,213). Important shortcomings of hybrid palliation include the potential for retrograde arch obstruction that can result in cerebral and coronary ischemia (246,247). This risk is highest among patients with an atretic aortic valve, and inter-stage interventional catheterization procedures are commonly required. Branch PA banding either alone or in combination with ductal stenting may also be useful for the patient at increased risk for CPB-related complications such as a neonate with an intracranial hemorrhage or the premature, low-birth-weight newborn (248).

Anesthetic Management

Trauma and surgical stress induce a neurohumoral and cytokine response, the magnitude of which is associated with organ dysfunction and death (249). Anesthetic techniques that reduce the magnitude of biologic markers of stress are associated with decreased mortality (250). Because of the extent of surgical trauma and the use of profound hypothermia with or without circulatory arrest, anesthetic techniques that use high doses of synthetic opioids to reduce the stress response and preserve the limited neonatal cardiac reserve are rational and associated with improved outcome (146,251). Typically, profound analgesia and adequate blunting of the stress responses can be accomplished with 30 to 60 $\mu\text{g}/\text{kg}$ of fentanyl before CPB and a continuous fentanyl infusion of

FIGURE 48.16. Kaplan-Meier curves for transplantation-free survival among all infants who underwent the Norwood procedure, according to the intention-to-treat analysis. Transplantation-free survival 12 months after randomization was higher with the RVPA shunt than with the MBTT shunt (74% vs. 64%, $p = 0.01$). 10 $\mu\text{g/kg/h}$ throughout the procedure and into the postoperative period (146,252). Low-dose volatile anesthetics (0.25 to 0.5 minimum alveolar concentration [MAC]) or benzodiazepines (lorazepam 100 to 200 $\mu\text{g/kg}$) for hypnosis and to further limit autonomic responses, particularly to CPB, are routinely used. Some patients may require dopamine at 2 to 5 $\mu\text{g/kg/min}$, or epinephrine or norepinephrine at 0.02 to 0.05 $\mu\text{g/kg/min}$ to counterbalance the reduction in sympathetic outflow resulting from profound unconsciousness, and such inotropic support will usually improve systemic flow to vital organs (253). Monitoring of regional circulation with NIRS is helpful to assess the complex circulatory changes that result from surgical and anesthetic effects in these patients, and can be applied noninvasively and continuously throughout the perioperative period.

Afterload Reduction

Anesthetic drugs alone cannot completely eliminate the stress response to profound hypothermia (146). Because increases in SVR as part of the stress response can impair systemic oxygen delivery, strategies to control Qp/Qs have been critical in the management of these infants. Medical gas management aimed at elevation of PVR with inspired CO_2 or hypoxic gas mixtures allows control of PVR independent of minute ventilation (167,173,177). Management based on modulating PVR guided by SaO_2 as an indicator of Qp/Qs does not eliminate early hemodynamic collapse, and autonomic influences on SVR remain active.

As an alternative approach to obtain Qp/Qs balance, pharmacologic interruption of systemic vasoconstrictor responses using α -adrenergic blockade was popularized by Poirier et al. (254). Such an approach has been shown to increase systemic oxygen delivery (179) and is associated with improved survival (179,180). The basic physiologic premise is that pharmacologic clamping of SVR in conjunction with clamping the total PVR with a resistive shunt will reduce the variability in systemic oxygen delivery through reduced variability in Qp/Qs. The importance of shunt size in limiting Qp/Qs extremes has been modeled, and smaller shunts make pulmonary overcirculation less likely (176). However, fourfold elevations in SVR are possible in the stressed neonate, making variable Qp/Qs unavoidable if the capacity for vasoconstriction is not blocked or at least reduced. Treatment with phenoxybenzamine, a long-acting irreversible α -adrenergic receptor blocker, improved systemic oxygen delivery as signaled by SvO_2 (178,255). The improved SvO_2 occurred during the early postoperative course, the time typically associated with critical reductions in systemic oxygen delivery (256,257). The relationship between blood pressure and SvO_2 was fundamentally altered in patients receiving phenoxybenzamine, suggesting that SVR was both lower and less variable (Figs. 48.17 and 48.18). With SVR effectively clamped by reducing autonomic influences, we found that phenoxybenzamine, compared to nitroprusside, largely eliminated the deterioration of systemic oxygen delivery at high SaO_2 and fundamentally changed the relationship between SaO_2 and SvO_2 in the postoperative parallel univentricular circulation, as depicted in Figure 48.19 (182). This has simplified management by reducing the extremes in Qp/Qs variability: the required total cardiac output to meet systemic oxygen requirements is less at Qp/Qs closer to one, and the cycle of increasing SVR resulting in falling oxygen delivery is interrupted. Our strategy had been to use 0.25 mg/kg phenoxybenzamine at the initiation of CPB, with a selective postoperative infusion of 0.25 mg/kg/day limited to infants who demonstrate reactive SVR despite fentanyl and benzodiazepine treatment, with benefits both from the specific pharmacologic effect of α blockade and from the prolonged duration of action,

FIGURE 48.17. Effect of phenoxybenzamine on 48-hour SvO_2 trend. Mean and 95% confidence intervals of SvO_2 from neonates following the Norwood procedure with and without phenoxybenzamine. Phenoxybenzamine increases SvO_2 and reduces variability. SvO_2 , systemic venous saturation. (Adapted from Tweddell JS, Hoffman GM, Fedderly RT, et al. Phenoxybenzamine improves systemic oxygen delivery following the Norwood procedure. *Ann Thorac Surg* 1999;67:161–168.)

which committed the patient to a treatment strategy that both promotes and requires high systemic blood flow. Because an intravenous formulation of phenoxybenzamine is no longer commercially available, we have more recently substituted phentolamine 250 $\mu\text{g/kg}$ bolus on CPB with a continuous infusion at 1 to 2 $\mu\text{g/kg/min}$ continued through the first 24 to 48 postoperative hours. Both phentolamine and phenoxybenzamine have improved indices of systemic perfusion compared to nitrovasodilators (258–260), and this effect is likely related to the specific distribution of vascular resistance achieved via α -adrenergic blockade.

Management of Cardiopulmonary Bypass

High-flow CPB guided by SvO_2 provides the best organ perfusion and the least metabolic evidence of anaerobic metabolism. However, reconstruction of the aortic arch requires that blood flow be intermittently interrupted, and thus circulatory support for stage 1 palliation typically entails some degree of regional hypoperfusion. In addition to the usual invasive monitoring and venous oximetry on CPB, two-site NIRS has been identified as a useful adjunct to guide management of the determinants of oxygen delivery and consumption on CPB.

CPB strategies vary by institutional philosophy and patient-specific anatomy as well as the intended operation. Both cannula placement and perfusion strategy are interdependent factors. Most commonly, a single venous cannulation is used. Direct cannulation of the proximal PA trunk or ductus arteriosus permits high-flow bypass to commence with the intent of whole-body cooling to 18°C to 20°C prior to circulatory arrest, after which time the arterial cannula is repositioned in the neo-aortic trunk (207,261). Alternatively, the innominate artery can be cannulated either directly or via a synthetic graft that will later become the source of pulmonary blood flow. This approach permits continuous cerebral perfusion with enough access to the arch to permit reconstruction and also provides measurable descending aortic blood flow (183,184,261,262). By manipulation of pump flows, temperature, and pCO_2 , significant somatic blood flow may be maintained during regional perfusion via the innominate artery (183,184,263). Avoidance of somatic arrest and profound hypothermia has also been achieved with bifurcated aortic cannulation to the innominate and DAO (264).

FIGURE 48.18. Effect of phenoxybenzamine on SvO_2 –blood pressure relationship. Real-time (hourly) values of SvO_2 and mean arterial blood pressure and linear fit equations from neonates after the Norwood operation. In neonates managed without phenoxybenzamine, blood pressure and systemic oxygen delivery are inversely related because blood pressure is determined mainly by SVR. In neonates who received phenoxybenzamine, blood pressure and oxygen delivery are positively related because blood pressure is determined mainly by cardiac output and SVR remains relatively constant. SvO_2 , systemic venous saturation. (Adapted from Tweddell JS, Hoffman GM, Fedderly RT, et al. Phenoxybenzamine improves systemic oxygen delivery following the Norwood procedure. *Ann Thorac Surg* 1999;67:161–168.)

Management of blood flow, hematocrit, temperature, and pCO_2 on CPB surrounding the time of circulatory arrest has been extensively investigated. Evidence suggests that cooling until jugular venous saturation is near 100%, at which time EEG silence occurs, maximally preserves cerebral oxygenation during subsequent ischemia. Neurologic outcomes

are presumably improved with longer cooling time, pH-stat management during cooling, higher hematocrit before and after deep hypothermic circulatory arrest (DHCA), and by providing more metabolic suppression from hypothermia with more oxygen delivery (265). Questions remain whether metabolic suppression from hypercapnia is additionally beneficial.

FIGURE 48.19. Effect of phenoxybenzamine on SaO_2 – SvO_2 relationship. Real-time (hourly) SaO_2 and SvO_2 values and best-fit polynomial equations in neonates after the Norwood procedure with and without phenoxybenzamine. The SaO_2 – SvO_2 pattern in control patients reveals variable Qp/Qs and a systemic-to-pulmonary flow tradeoff at high SaO_2 ; a critical peak of SvO_2 occurs at an average SaO_2 of 77%. In contrast, the SaO_2 – SvO_2 relationship follows the pattern of variable total output and relatively constant Qp/Qs with phenoxybenzamine treatment, with no evidence of systemic-to-pulmonary flow tradeoff. However, individual SvO_2 cannot be predicted from SaO_2 in either group. Qp , pulmonary blood flow; Qs , systemic blood flow; SaO_2 , oxygen saturation; SvO_2 , systemic venous saturation. (Adapted from Hoffman GM, Tweddell JS, Ghanayem NS, et al. Relationship between arterial and venous saturation following the Norwood procedure: sustained afterload reduction prevents hemodynamic deterioration at high arterial saturation. *J Thorac Cardiovasc Surg* 2004;127:738–745.)

The absolute safe time for DHCA in any individual patient remains unknown, although risk is clearly increased after 30 to 40 minutes at 18°C to 22°C (266). Neurologic injury, however, may occur despite all CPB parameters in the usual safe range. Anttila et al. (267) have shown that combinations of hematocrit, pCO₂, temperature, and flow rate could produce ischemic injury, which was consistently identified by a lower brain oxygen saturation by NIRS. Based on the premise that hypoxia is the major cause of cerebral injury in the perioperative period, it is hypothesized that strategies that provide continuous or near-continuous cerebral perfusion (268) may avoid the complications attributable to DHCA (269). A recent randomized prospective study of patients with single-ventricle anatomy undergoing arch reconstruction comparing DHCA to low-flow (10 mL/kg/min) continuous cerebral perfusion failed to identify a difference in neurodevelopmental outcome at 1 year of age (270). That study, although well designed from a structural viewpoint, unfortunately chose a flow rate for continuous cerebral perfusion below that which is required (40 to 60 mL/kg/min) to ensure adequate cerebral blood flow and oxygen delivery (271,272), and thus its findings cannot be generalized to answer the important question that it was designed to answer. A post-CPB period of increased risk of decreased cerebral perfusion has been identified (Fig. 48.20), and intraoperative strategies can influence postoperative cerebral hemodynamics in subtle but important ways (272). Because techniques are continuously evolving, and neurologic outcome assessment is best performed many years after neonatal surgery, a formal outcome study will not likely speak directly to current management.

During rewarming and reperfusion, oxygen consumption increases and may require adjustment of flow by physiologic parameters. Titration of hypnotic drugs may be necessary to limit both oxygen consumption and vascular responses. Ultrafiltration during rewarming should aim to raise the hematocrit to 40%. Uniform rewarming to a bladder temperature of 36°C is necessary to avoid thermoregulatory metabolic responses after separation from CPB, which will be imposed at the most critical point for oxygen delivery. Additional targets include an SVR of about 12 Wood units and anesthetic and inotropic support at a steady state. Before separation from CPB, milrinone (50 µg/kg load plus infusion of 0.5 µg/kg/min) is routinely used for inodilation (273). With pump flow of 3.2 L/m²/min, an organ perfusion pressure of 40 mm Hg (mean arterial pressure [MAP] – central venous pressure [CVP]) is targeted while the systemic-to-pulmonary artery shunt is still occluded. This translates into a systemic vascular resistance

index (SVRI) of 12 Wood units. Anesthetic depth is evaluated, but analgesic/hypnotic withdrawal is not used to raise SVR. Specifically, low-dose vapor or hypnotic infusion is maintained during rewarming, separation from CPB, and closure. If the SVR is low, as is typical with the use of phenoxybenzamine, norepinephrine is infused at 0.03 to 0.3 µg/kg/min. For additional inotropy, epinephrine in the 0.03 to 0.3 µg/kg/min range is titrated to systolic function and heart rate (169,257). If SVR is high, additional sedative/hypnotic, alpha-blockade, or, rarely, nitroprusside is administered. If phenoxybenzamine or phentolamine has been administered on CPB, then additional epinephrine often reduces SVR because of unopposed β-adrenergic activity in the face of α-adrenergic blockade.

Once the target SVR has been achieved and vasoactive infusions are constant, the lungs are reinflated and mechanical ventilation is resumed. Usual initial ventilator settings include a FiO₂ >0.5, inflating pressure of 25 to 28 cm H₂O, inspiratory time of 0.6 to 0.8 seconds, PEEP of 3 to 4 cm H₂O, and a rate of 10 to 20 breaths per minute to achieve normal alveolar ventilation without atelectasis. Prolonged ventilation without lung perfusion is avoided to reduce the likelihood of acute changes in PVR and lung injury (274–276). Shunt adequacy is evaluated with a test opening; a rise in end-tidal CO₂ to the 30-torr range and a drop in MAP of >10 mm Hg are suggestive of adequate shunt flow. An oximetric catheter may be placed in the SVC for post-CPB monitoring. Weaning from CPB is attempted over 30 to 45 seconds. The total cardiac output must double with shunt opening; preload must be carefully titrated to avoid ischemia and generally is optimal at an initial CVP of 10 to 12 mm Hg. Inotropic support may need further adjustment during this time. As pump flow decreases, the arterial and venous saturation falls. Generally, an organ perfusion pressure of 40 mm Hg is adequate. Real-time knowledge of Qp/Qs and direct or NIRS-surrogate SvO₂ drive physiologic adjustment of SVR and myocardial performance. SvO₂ or other measures of oxygen supply/demand become the primary hemodynamic target, with appropriate attention to coronary perfusion pressure and evidence of ischemia.

Successful separation from CPB is likely if arteriovenous saturation difference remains normal (20% to 30%) and SvO₂ remains above the anaerobic threshold of 30% to 35%. Modified ultrafiltration usually increases SvO₂ and apparent myocardial performance (277). A low SvO₂ (<40%) with high SaO₂ (>80%) indicates high Qp/Qs, and reduction in SVR is attempted. Increasing PaCO₂ may redistribute systemic blood flow to the brain but has little effect on Qp/Qs in the postoperative period in the presence of a relatively restrictive systemic

FIGURE 48.20. Changes in cerebral and somatic saturation during the Norwood procedure performed with continuous cerebral perfusion. Frontal cerebral and T10-L2 flank (renal-somatic) regional saturation (rSO₂) from continuous NIRS monitoring during the Norwood procedure. Cerebral oxygenation is well maintained during continuous regional cerebral perfusion (RCP) via the innominate artery, but somatic saturation falls. After weaning from cardiopulmonary bypass (CPB), the cerebral saturation falls, although somatic oxygenation is maintained. (Adapted from Hoffman GM, Stuth EA, Jaquiss RD, et al. Changes in cerebral and somatic oxygenation during stage 1 palliation of hypoplastic left heart syndrome using continuous regional cerebral perfusion. *J Thorac Cardiovasc Surg* 2004;127:223–233.)

TABLE 48.2 Circulatory Management based on SvO₂ Interpretation

SaO ₂	SvO ₂	Qp/Qs	Suggested Intervention
80	60	1.0	None; slowly wean support
80	40	2.0	Sedation/analgesia, warmth, vasodilator
70	50	0.67	Resolve atelectasis, raise SVR
70	40	1.0	Raise cardiac output, raise hemoglobin, reduce VO ₂
75	25	2.0	Raise cardiac output, lower SVR
60	40	0.5	Resolve atelectasis, raise SVR, consider iNO, consider shunt augmentation
87	70	1.5	Wean support
87	40	3.6	Sedation/analgesia, vasodilation, consider shunt restriction

to pulmonary shunt. Low SvO₂ and balanced Qp/Qs indicate inadequate total oxygen delivery. Increasing the inotropic state, preload optimization, increasing hemoglobin, and metabolic suppression can be used. High SVR must be addressed and may be present even if blood pressure is not high because of the accompanying reduction in systemic perfusion. Management based on SvO₂ or NIRS as a surrogate is shown in Table 48.2. Using cerebral (rSO₂C) and somatic (rSO₂R) NIRS approximations of regional venous saturation, the arteriovenous difference across brain and kidney, muscle, or gut can be continuously assessed and regional blood flow changes derived from application of the inverse Fick principle, allowing appropriate interventions directed at pulmonary, cerebral, and systemic blood flows specifically. Current targets include an SaO₂ >80%, SvO₂ >50%, cerebral arteriovenous difference of 20% to 30% and rSO₂C >50%, somatic arteriovenous difference of 10% to 20% and somatic rSO₂R >70%, CVP of 9 to 12 mm Hg, and MAP of 48 to 52 mm Hg (188,191,272,278).

After separation and completion of modified ultrafiltration, cannulae are removed and heparin reversal is achieved. Modification of Qp/Qs by PVR modulation is now less effective than manipulation of SVR because of the large fixed resistance imposed by the systemic-to-pulmonary artery interposition shunt and the potential lability in SVR. Lung management targets the usual goals of maintenance of functional residual capacity, avoidance of atelectasis, and fully saturated pulmonary capillary blood. In the presence of a restrictive shunt, adjustment of CO₂ will have more effect on the distribution of SVR than on total pulmonary resistance (176), and increasing the FiO₂ will usually increase oxygen delivery without adverse effect on Qp/Qs (177). Increases in SaO₂ are not deleterious in the presence of intense afterload reduction (182). Because changes in SVR, sympathetic outflow, and oxygen consumption with volatile anesthetic withdrawal can pose physiologic threat in these patients, transition to an intravenous hypnotic and analgesic strategy should occur before transfer to the ICU.

Mechanical Circulatory Support

Mechanical circulatory support should be initiated before global or regional hypoxia results in organ damage or death. The threshold for brain lactate production occurs with cerebral rSO₂ values around 40% (279,280), and the threshold for anaerobic metabolism appears to be at an SvO₂ around 30% in this patient population (181). If manipulation of

SVR, PVR, and inotropic state does not result in adequate systemic oxygen delivery, and if there is no issue with shunt size, patency, or other correctable anatomic limitations, then inotropic support should be aggressively escalated since individual dose-response effects are variable. Adequate oxygen delivery is the goal (257). Failure to achieve adequate organ oxygen delivery with sustainable inotropic support should prompt consideration of mechanical support. Elective mechanical support should be considered a defensible strategy and preferable over unplanned circulatory collapse and resuscitation (281). Treatment of the patient with single-ventricle physiology in the arrest and prearrest situation has recently been reviewed (282,283), with emphasis on SvO₂ and NIRS monitoring for assessment and continuous guidance about response to interventions.

Traditional venoarterial extracorporeal membrane oxygenator (ECMO) support must be used if there is any question about shunt patency or lung function, and rapid-response ECMO can effectively salvage some infants who have severe hypoxia and cardiogenic shock. Management of the systemic-to-pulmonary artery shunt on ECMO has evolved. Historically, the shunt was mechanically clipped during ECMO support (238). This strategy was used because of a desire to limit ECMO flow and concerns about excessive pulmonary blood flow hypothesized to result in pulmonary dysfunction while on support. The result of a clipped shunt strategy was development of pulmonary dysfunction, which has been postulated to be due to ischemia or more likely severe alveolar alkalosis that resulted from prolonged ventilation of underperfused lungs. Management with a patent shunt allows for gradual transition to pulmonary gas exchange while support flow is weaned (284). An alternative approach to mechanical support is to use the patient's lungs' total gas exchange, and a roller pump without oxygenator is interposed between atrial drainage and the aorta (285). This arrangement simplifies anticoagulation and requires maintenance of lung ultrastructure and function, which may be impaired by ECMO without pulmonary blood flow (276). Use of mechanical support to preserve end-organ function may improve outcomes (73,281,285). Problems with ECMO include bleeding, clotting, massive blood product requirements, lung "whiteout," acquired adult respiratory distress syndrome (ARDS) from ventilating an ischemic lung, and intracranial bleeding.

We prefer a technique that maintains shunt patency allowing continuous transition of circulatory work and gas

exchange between the patient and the machine. Critical attention to fluid and colloid administration with maintenance of CVP < 10 is necessary if pulmonary and myocardial function are to recover. Continued management of SVR may be necessary to maintain adequate organ perfusion pressure and regional blood flow. CO₂ is added to the inspired gas during ECMO to achieve an end-tidal CO₂ of 40 torr to avoid hypocapnic lung injury (275,276) and acute increases in PVR with lung reperfusion (274). This strategy allows progressive weaning of mechanical support as native myocardial function improves.

Postoperative Management

Unbalanced Qp/Qs, reduced total cardiac output, higher oxygen demand, and the potential for myocardial ischemia contribute to morbidity and mortality. Oxygen delivery is limited by myocardial edema with attendant diastolic dysfunction and the potential development of tamponade physiology (286–288). This physiologic vulnerability peaks in the first 6 to 12 hours postoperatively, and all monitoring appropriate for the operating room should be maintained throughout this period (122,257). Postoperative management should target adequate organ oxygenation including stabilization of oxygen consumption to reduce morbidity and mortality. Strategic improvements in oxygen delivery have paralleled improved survival (289) and neurologic outcomes (290) in our series. SvO₂ and NIRS data as primary markers of systemic oxygen delivery are used targeting SvO₂ > 50%, cerebral rSO₂ > 50%, and somatic rSO₂ > 60% to minimize organ dysfunction and the risk of secondary multisystem organ dysfunction (181,278,291). Evidence of anaerobic metabolism with SvO₂ approaching 30% has been demonstrated, and management strategies that target a SvO₂ of >50% have reduced mortality (73,181,292).

Delaying sternal closure until postoperative day 2 to 4 has reduced early hemodynamic compromise and the need for mechanical circulatory support (293). The development of moderate tamponade physiology is expected. Therefore, the procedure should be timed such that inotrope-recrutable stroke volume is available. An increase in inflammatory responses including elevated temperature setpoint is expected after sternal closure, with possible need for additional support.

An increase in oxygen consumption of about 30% can be expected with the transition to spontaneous ventilation. Pharmacologic support should be adjusted during this transition as appropriate. Excessive work of breathing owing to altered mechanics will quickly destabilize the circulation.

Interstage Management and the Timing of Stage 2 Palliation

After recovery from stage 1 palliation, acute care is transitioned to chronic therapies that allow preservation of organ function and somatic growth. As such, interstage management should include pharmacologic therapy targeted at optimizing the inefficient parallel circulation inherent to HLHS after stage 1 palliation, vigilant monitoring of physiologic variances as a means to identify destabilizing pathology, and ensuring adequate nutrition and somatic growth.

Prescribed Medical Therapy

Pharmacologic therapy between stages 1 and 2 palliation remains variable among institutions and potentially includes chronic afterload reduction, diuretics, and/or digoxin for support of the cardiovascular system, and anticoagulation. Chronic afterload reduction with an angiotensin-converting enzyme (ACE) inhibitor may be beneficial in patients who

have a pulmonary-to-systemic flow ratio (Qp/Qs) > 2 in the early postoperative period, greater than mild atrioventricular valve insufficiency, evidence of congestive heart failure, or noninvasive evidence of elevated SVR. If SVR is suboptimally controlled with ACE-inhibitor therapy, enteral or transdermal clonidine may be effective. Afterload reduction is titrated with caution to avoid worsening hypoxia from excessive lowering of the Qp/Qs ratio and diastolic hypotension that could result in impaired coronary flow. For patients with evidence of pulmonary overcirculation or heart failure, chronic diuretic therapy with furosemide is prescribed. Caution is taken to avoid intravascular volume depletion that might reduce total cardiac output as well as increase the risk of shunt thrombosis owing to hyperviscosity. Prophylactic antiplatelet therapy with aspirin 20 mg daily is uniformly administered to our patients unless there is evidence of atrial or venous clot, at which time subcutaneous low-molecular-weight heparin is prescribed with a therapeutic goal of 0.7 to 1.2 anti-Xa IU/mL. Finally, patients at our institution are expected to maintain SaO₂ >78% while awake and asleep, and if unable to do so, are placed on supplemental oxygen via nasal cannula. Any one of these prescribed therapies will likely require outpatient adjustments during the interstage period.

Risk Factors for Interstage Death

The limited circulatory reserve inherent in a volume-loaded single ventricle with parallel circulation and cyanosis places the infant with HLHS at risk for late morbidity and mortality. The incidence of sudden death in the interstage period has remained fairly constant at approximately 5% to 15% and does not seem to have been eliminated despite the introduction of perioperative surgical, medical, and monitoring strategies that have dramatically improved early inpatient survival (73,179,228,241,294–296).

Multiple risk factors and causes have been proposed for interstage death. Escalated risk of interstage mortality has been linked to anatomic diagnosis and residual or recurrent lesions. Specifically, the diagnosis of aortic atresia with a diminutive ascending aorta represents an anatomic subtype of HLHS presumably with the lowest physiologic reserve and has been associated with an increased risk of late death (219,254,297). The presence of a restrictive atrial communication, arch obstruction, obstructed shunt flow, PA distortion, atrioventricular valve insufficiency, and arrhythmias have also been associated with interstage mortality (215,217,228,232,295,296). Commonly acquired childhood gastrointestinal or respiratory diseases that result in hypovolemia and/or acute hypoxemia have also been implicated as causes for interstage death (71,217). After successful stage 1 palliation, any of the above-mentioned pathologic processes can lead to increased metabolic demands and an unfavorable oxygen supply/demand relationship, placing the infant with minimal myocardial reserve at even greater risk for mortality until progression to cavopulmonary anastomosis. Therefore, transitioning infants to home after stage 1 palliation warrants ongoing vigilance well beyond the initial early postoperative period and requires continued collaboration among caregivers, including parents.

Interstage Monitoring

To improve late outcomes, we developed an interstage monitoring program of SaO₂ and weight designed for home use as a means to identify modifiable risk factors that might fatally tax the inefficient circulation intrinsic to HLHS after stage 1 palliation (71). The monitoring program was based on the hypothesis that earlier recognition of decreased SaO₂ from baseline, poor weight gain, or weight loss might foretell the presence of

serious anatomic lesions or a developing intercurrent illness and subsequently allow for lifesaving intervention during the interstage period.

In infants with HLHS after stage 1 palliation, arterial desaturation from baseline might be indicative of anemia, respiratory illness, and myocardial dysfunction resulting from falling cardiac output, or limited pulmonary blood flow from shunt stenosis or outgrowth. Hypoxemia alone, however, might not occur early in an acute illness that results in elevation in SVR, with consequent reduced systemic flow and increased Qp/Qs. Specifically, dehydration that results in hypovolemic shock from increased fluid loss as seen with gastroenteritis or decreased intake might mimic such a clinical scenario and be reflected only by failure to have expected weight gain or even weight loss.

To detect acute hypoxemia, dehydration, or growth failure between stages 1 and 2 palliation, patients are discharged home with a digital infant scale and pulse oximeter as part of an interstage monitoring program, and parents obtain daily weights and oxygen saturations. Criteria for which parents are instructed to notify a member of the cardiac team are $\text{SaO}_2 < 75\%$ or $>90\%$, weight loss of 30 g, failure to gain 20 g of weight over 3 days, or enteral intake $<100 \text{ mL/kg/day}$. Breach of criteria prompts investigation to rule out an intercurrent illness or anatomic lesion as the cause of physiologic variance.

Initiation of interstage monitoring in September 2000 marked another milestone in the palliation of HLHS with improved interstage survival from 84% to 99% in a cohort of 139 patients who underwent stage 1 palliation with 95% early survival. Just over half of the monitored patients breached surveillance criteria with most patients presenting before 100 days of age. Worsening hypoxemia was the most common reason parents sought medical care. Shunt stenosis, outgrowth of the shunt, and innominate artery narrowing represented the cardiac diagnoses that led to interstage hypoxemia. Extracardiac causes of desaturation from baseline included viral illness, anemia, and dehydration. Isolated inappropriate weight change or generally poor weight gain occurred in a third of patients who breached surveillance criteria and was the result of recurrent arch obstruction, sepsis, poor oral intake necessitating gastrostomy tube placement, failure to adequately adjust gastrostomy tube feeds for weight gain, or progressive heart failure (233).

Nutritional Support and Somatic Growth

Adequate nutritional support and growth are important in the patient with univentricular circulation and planned surgical palliation. Specifically, preoperative hypoalbuminemia is associated with increased postoperative infection rates, longer hospital stays, and increased mortality (298). Poor interstage growth velocity and lower weight-for-age z-score at bidirectional cavopulmonary anastomosis predicts a more complex postoperative course and longer hospital stay (299,300). Studies to date report that 50% of infants with HLHS are malnourished in infancy with weight-for-age z-score <-2 or with an early infancy growth velocity $<20 \text{ g/day}$ (299–301). Etiology for growth failure in these patients is multifactorial and may include heart failure, extracardiac anomalies, genetic syndromes, gastrointestinal dysmotility, and/or malabsorption, any of which may contribute to inadequate enteral intake for energy utilization and growth.

Scrutiny of weight change during early infancy provided invaluable somatic growth data for this patient population. From >1,400 patient weight observations, a growth curve was generated for infants who survived the interstage period. Unlike the healthy infant who usually doubles the birth weight by 5 months of age, the patient with HLHS appears to have limited growth potential with a plateau phase of weight gain between 4 and 5 months of age (Fig. 48.21). Early growth velocity was generally $<20 \text{ g/day}$ whereas normal infant growth is 25 g/day . These initial data prompted a greater focus on ensuring adequate caloric intake prior to hospital discharge and increased attention to outpatient growth and nutrition. In an attempt to optimize adequate growth, infants are expected to take 110 to 130 kcal/kg/day with formula or breast milk fortified to 24 to 27 calories per ounce. Approximately, 25% of our patients have undergone open gastrostomy tube placement because of inability to consume adequate calories with oral feeding alone. Increased attentiveness to nutritional intake at our institution has resulted in improved somatic growth in monitored patients that nearly parallels normal infant growth with a growth velocity $>25 \text{ g/day}$ and an increase in weight for age z-score from -1.3 at hospital discharge after the Norwood procedure to -0.9 at stage 2 palliation.

Attentiveness to nutritional support also provided insight into optimal timing for stage 2 palliation. When comparing interstage monitored patients with those patients who were

FIGURE 48.21. Interstage growth among survivors of the stage 1 palliation calculated using > 1,400 observations of weights. The regression line and 95% confidence intervals are indicated. Normal growth is depicted in the shaded area, with the dashed line representing 50% for age. The curve indicates the limited growth potential of the patient following the first stage of palliation. In this group of patients, growth into later infancy is limited, unlike a normal infant whose continued growth is expected. (Reproduced from Ghanayem NS, Tweddell JS, Hoffman GM, et al. Optimal timing of the second stage of palliation for hypoplastic left heart syndrome facilitated through home monitoring, and the results of early cavopulmonary anastomosis. *Cardiol Young* 2006;16:61–66, with permission.)

FIGURE 48.22. Connection of the SVC to the pulmonary arteries and takedown of previous systemic-to-PA shunts constitute the stage 2 procedure. Two surgical techniques are commonly used. **A:** The bidirectional Glenn shunt is a direct anastomosis of the SVC to the central PA. The principle advantage of the bidirectional Glenn shunt is the ease of construction; it can even be accomplished without the use of CPB in selected cases. **B:** In a hemi-Fontan procedure, the SVC is connected to the confluent pulmonary arteries without disconnecting it from the atrium; the atrial end of the SVC is closed with a patch. Although a more extensive operation than the bidirectional Glenn shunt, the hemi-Fontan allows for expeditious performance of a completion Fontan.

A Bidirectional Glenn

B Hemi-Fontan

not subjected to frequent monitoring of weight and saturation, monitored patients had similar weights to nonmonitored patients (5.5 ± 0.8 vs. 5.7 ± 1.3 kg) despite the younger age at stage 2 palliation in the monitored group (4.2 ± 1.4 vs. 5.6 ± 2.1 months, $p < 0.01$). This observation, along with the demonstrable flattening in growth velocity beyond 4 to 5 months of age call into question the benefit of arbitrarily delaying stage 2 palliation until after 6 months of age.

Stage 2: Superior Cavopulmonary Connection

Superior cavopulmonary anastomosis prior to completion Fontan improves ultimate survival and is associated with low operative and late mortality (219,302). In this operation, CPB is usually employed to allow anastomosis of the SVC to the proximal ipsilateral PA and takedown of prior shunts placed to provide pulmonary blood flow (Fig. 48.22). Anesthetic management usually includes a more balanced anesthetic technique that avoids prolonged postoperative ventilation, and approaches that include neuraxial opioids may have a favorable effect on early postoperative management (303). Progression to the cavopulmonary anastomosis reduces both wall stress and atrioventricular valve insufficiency through elimination of the volume load on the single systemic ventricle. It creates a more efficient in-series circulation and increases diastolic pressure with improved coronary artery perfusion (208,221,294). The delayed timing of stage 2 palliation to 6 months of age has been supported by previous reports that early cavopulmonary anastomosis has been associated with severe hypoxemia, prolonged pleural drainage, PA thrombosis, poor PA growth, early development of pulmonary arteriovenous malformations, and excess mortality (304–307). However, it seems logical that by simply shortening the period of risk linked to the inefficient parallel circulation after stage 1 palliation, interstage survival will be enhanced.

In a series of home-monitored patients, those who breached home-monitoring criteria proceeded to stage 2 palliation at a significantly younger age of 3.6 ± 1 months compared with 5.6 ± 2.1 months for those receiving conventional management ($p < 0.01$) (71). Despite the younger age at stage 2 palliation of the monitored patients, weights between groups were similar: 5.3 ± 0.9 versus 5.7 ± 1.3 kg ($p = ns$). The success of early cavopulmonary anastomosis in these patients deemed at greatest risk for interstage mortality has modified our overall practice in that stage 2 palliation is electively performed at 4 months of age or earlier if necessary.

The implications of early cavopulmonary anastomosis have been further reviewed by Jaquiss et al. (307,308). Patients who underwent cavopulmonary anastomosis at <4 months of age (mean 3.1 ± 1.4 months) were compared with their older counterparts (mean 5.5 ± 1.5 months). All patients survived with an actuarial survival of 96% at 1 year in both groups. The younger group, however, required prolonged mechanical ventilation, had a greater duration of pleural drainage, and had a longer hospital stay. Younger patients also had lower oxygen saturations postoperatively compared with the older group, but by hospital discharge, groups had similar oxygen saturations (307). Follow-up data on this cohort demonstrated no difference in late complications, preoperative hemodynamics at the time of Fontan palliation, or status of the patient after completion Fontan (308).

After the stage 2 operation, patients experienced improved activity and physiologic reserve, which lasted several years. However, increasing cyanosis following stage 2 palliation is predictable and is due to several factors including increased lower-body growth and oxygen consumption with concomitant increase in desaturated inferior vena caval blood return. Patients will also develop venovenous collaterals from the high-pressure SVC to veins ultimately draining to the IVC or atrium. Furthermore, patients are at risk for the development of arteriovenous malformations that result in intrapulmonary shunting of blood from PA to pulmonary vein without gas exchange. These are postulated to be the result of a lack of so-called hepatic factor, which prevents the shunt formation (309). Pulmonary arteriovenous malformations can be reversed by the completion Fontan operation, presumably by restoring hepatic factor to the pulmonary circulation.

Stage 3: Completion Fontan

For the patient with HLHS, the Fontan procedure is the last anticipated operation. The techniques and indications for surgery are not different from those for other single-ventricle patients, and indeed in many centers patients with HLHS make up the majority of patients undergoing the completion Fontan. For patients who have undergone a stage 2 procedure, either a bidirectional Glenn shunt or hemi-Fontan, the timing of completion Fontan is not critical; in general, the operation is performed between 18 months and 4 years of age, with anesthetic considerations similar to those for the stage 2 operation. The surgical goal is to route the blood from the IVC to the pulmonary arteries with as little energy loss as possible. Although interventional techniques to perform the completion Fontan using coated stents have been reported, much more commonly,

FIGURE 48.23. The completion Fontan operation can be accomplished in two ways. **A:** The lateral tunnel Fontan involves creating an intra-atrial baffle that connects the IVC to the pulmonary arteries. **B:** The extracardiac Fontan uses a tube graft to connect the IVC to the central PA. In both cases, all caval return with the exception of the coronary sinus is directed to the pulmonary arteries, simulating as closely as possible the normal circulatory pattern. To improve hemodynamics, especially in the early postoperative period, a fenestration is often placed between the baffle or conduit and the pulmonary venous atrium. This decreases CVP and increases preload to the single ventricle, albeit at the cost of some systemic desaturation.

this is performed in the operating room using one of two techniques; a lateral tunnel or extracardiac conduit (Fig. 48.23).

The lateral tunnel Fontan is commonly performed following the hemi-Fontan. As part of the hemi-Fontan, a dam is constructed between the pulmonary arteries and the RA. During the completion Fontan, this dam is removed and a section of prosthetic conduit is used to create a baffle to route the inferior caval blood return to the PA. The baffle is not circumferential, and a portion of the tunnel is made up of the patient's atrium, therefore maintaining, in theory, potential for growth. Additional advantages include a low level of power loss as determined by computational fluid dynamic studies (310). Although controversial, some studies suggest a higher incidence of sinus node dysfunction following the lateral tunnel Fontan (311–315). Another potential disadvantage of the lateral tunnel Fontan involves the presence of prosthetic material exposed to the pulmonary venous portion of the atrium with the potential for thrombus formation and systemic embolization.

The extracardiac Fontan is constructed by placing a prosthetic conduit between the IVC and the pulmonary arteries. The advantages include the ease of the operation and, although somewhat controversial, probably a lower incidence of sinus node dysfunction (311–315). In addition, no prosthetic material is placed in the pulmonary venous atrium, with potentially lower risk of thromboembolic complications. The principle disadvantage is the lack of growth potential. To this end, larger conduits, between 20 and 22 mm in diameter, are placed to accommodate growth. The larger and longer conduits may result in power loss, which, when combined with the potential for late revision for outgrowth, may impact the durability of the extracardiac Fontan.

The postoperative course of patients following the Fontan procedure for HLHS is not substantially different from that of other single-ventricle patients with equivalent function. Patients with HLHS more commonly have decreased systolic and altered diastolic function, and they are at increased risk for postoperative complications including decreased cardiac output with elevated CVP, pleural effusions, ascites, thrombosis, and arrhythmias. We routinely use a fenestration in the Fontan to permit right-to-left shunting, which decreases CVP and improves single-ventricle preload and cardiac output, at the expense of some degree of desaturation. The use of a fenestration has resulted in excellent survival and shorter hospital stay (206). Additional strategies that minimize postoperative hospital stay include routine use of the diuretics including spironolactone, an aldosterone antagonist, and furosemide. Supplemental oxygen is used as a pulmonary vasodilator, and afterload reduction is given to improve cardiac output and lower single-ventricle filling pressures (316).

Outcomes for Staged Palliation

Most mortality associated with the staged surgical approach occurs during and after stage 1 palliation, with recent cumulative early and interstage mortality in the 5% to 30% range (73,241,317,318). Improved outcome has been associated with early diagnosis, preoperative stabilization, early repair, systematic management approaches, and increased monitoring both in hospital and at home (71,73,294). The recent multi-institutional study comparing the modified Blalock-Thomas-Taussig shunt (MBTTS) to an RVPA conduit revealed that the early mortality was lower with the RVPA conduit approach; however, the variation in mortality across centers was a more significant factor than the type of shunt. The potential early advantage of the RVPA connection may result from a lower incidence of shunt thrombosis and associated mortality, with little improvement in systemic (233) or cerebral (235) hemodynamics.

Patient-related characteristics are increasingly recognized as risk factors for early and intermediate mortality after stage 1 palliation. Few studies have reported worsened outcomes in patients with prematurity, low birth weight, extracardiac anomalies, genetic syndromes, and/or additional cardiac anomalies. Patients with any of these characteristics have been designated as “high risk” for staged palliation due to early operative mortality rates of 30% to 50% compared to 10% to 15% operative mortality in patients without any of the aforementioned characteristics, the “standard-risk” cohort (75,319). We recently reported that intensive perioperative monitoring, early goal-directed treatment of shock, and greater resource utilization offset the vulnerability of “high-risk” patients resulting in comparable operative survival in “high-risk” and “standard-risk” patients, 87% versus 95%, respectively. In this series, ability to achieve stage 2 palliation or progression to transplant in lieu of stage 2 palliation was comparable between risk groups. Yet, “high-risk” patients had lower 1-year survival (78% vs. 93%) and survival to date (71% vs. 92%) compared to “standard-risk” patients (191). (see Fig. 48.24). Overall, for this cohort of 162 consecutive patients, operative survival was 91%, 1-year survival was 90%, and survival at last follow-up was 86%.

Cardiac Catheterization

Indications for cardiac catheterization in patients with HLHS may be either interventional in nature or may be elective studies performed prior to stage 2 palliation or prior to the Fontan connection.

FIGURE 48.24. Actuarial survival following Norwood palliation for standard-risk and high-risk patients from September 2000 to September 2008. Operative survival and survival to cavopulmonary anastomosis are comparable between groups. One-year survival and survival to date are lower in high-risk patients compared to standard-risk patients ($p = 0.01$ and 0.001 , respectively). (Reprinted from Ghanayem NS, Hoffman GM, Mussatto KA, et al. Perioperative monitoring in high-risk infants after stage 1 palliation of univentricular congenital heart disease. *J Thorac Cardiovasc Surg* 2010;140:857–863, with permission from Elsevier.)

Ruiz et al. (320) and Gewillig et al. (321) have reported on the use of transcatheter stent placement within the ductus arteriosus in newborns with HLHS. This was performed in a group of patients that were listed for cardiac transplantation. This intervention allowed avoidance of long-term PGE1 therapy and its inherent complications including apnea, increased secretions, and chronic edema in patients who may wait weeks to months for a donor heart. Transcatheter ductal stenting is also performed as part of the hybrid procedure for HLHS. Transcatheter atrial septostomy is also employed in patients with HLHS and an intact or highly restrictive atrial septal defect. It is likely that this group of patients has irreversible changes in PVR that may not respond to intervention after birth. As a result, few centers are currently performing fetal intervention procedures including balloon atrial septostomy in select patients with HLHS. Interventional procedures after stage 1 palliation may be indicated prior to stage 2 palliation. Indications for interventional catheterization include excessive cyanosis as a result of stenosis of the systemic-to-pulmonary artery shunt, stenosis of the right ventricular-to-PA conduit, or recurrent arch obstruction.

Diagnostic catheterization is routinely performed prior to stage 2 palliation in most centers. Information obtained includes measurement of PA pressure, pulmonary capillary wedge pressure, right ventricular systolic and diastolic pressure, and pressure in the ascending and descending aorta. In addition, the PA anatomy, the adequacy of the atrial septal defect, neo-aortic arch obstruction, atrioventricular valve function, right ventricular function, and SVC anatomy are assessed. Some studies suggest that in select patients in whom clinical or anatomic concerns are absent by history, physical exam, and echocardiography, cardiac catheterization may not be necessary prior to stage 2 palliation.

Finally, interventional cardiac catheterization may be necessary after stage 2 palliation. Indications may include excessive hypoxemia after stage 2 palliation with the requirement for catheter occlusion of a venovenous collateral or less commonly, intervention for either a stenotic cavopulmonary connection or branch PA. Catheter intervention for aortic arch narrowing may also be occasionally necessary after stage 2 palliation (217,302).

Catheterization is routinely performed prior to the completion Fontan operation at some centers. At this study, determination of PA pressure, pulmonary capillary wedge pressure, and ventricular end-diastolic pressure is performed. In addition PA anatomy, neo-aortic arch anatomy, and the presence of venovenous or aortopulmonary collaterals are assessed. Some centers use cardiac MRI and less frequently 3-D CT scanning to determine the cardiovascular anatomy in select patients and do not routinely perform a catheterization study prior to completion Fontan operation (322). Cardiac catheterization following the Fontan operation may be necessary if there are anatomic or physiologic concerns not easily elucidated by noninvasive imaging techniques. Some centers routinely perform cardiac catheterization 6 to 12 months after the Fontan procedure with consideration for fenestration closure following hemodynamic assessment.

Finally, completion Fontan operation itself has been performed via catheter intervention (323). For patients with planned Fontan completion via interventional catheterization, a modification of the hemi-Fontan procedure is performed and includes a restrictive band that is placed at the superior venacava–right atrial junction. A transseptal needle perforation is undertaken through the banded SVC–right atrial junction with the subsequent placement of a covered stent from the IVC to the PA. In a report of five patients who underwent the Fontan operation with this technique, all returned home in 24 hours; however, several patients required subsequent intervention for baffle leak (213).

Late Fontan Concerns

Staged palliation for single-ventricle physiology has undergone a series of surgical revisions that have reduced early postoperative Fontan mortality from 20% to <2% (324,325). In late follow-up studies, 11% of Fontan survivors were found to have clinically significant morbidity including atrial dysrhythmias, protein-losing enteropathy (PLE), liver dysfunction, congestive heart failure, progressive ventricular dysfunction, or stroke at a median age of 8 years (range 1 to 25 years). Despite the significant morbidities associated with the Fontan operation, overall late mortality (range 4 months to 18 years) continues to decrease from 25% in the early experience to 5% in the recent era (325,326). Although long-term outcome data are sparse for isolated HLHS, when compared to other single-ventricle lesions with Fontan circulation, late mortality is comparable regardless of ventricle morphology (206,327).

Over the recent decades, indications for successful Fontan have been modified from the initial “Ten Commandments” described by Choussat and Fontan. From this list, specific physiologic risk factors for a failing Fontan prevail and relate to ventricular performance, atrioventricular and aortic valve function, and pulmonary circulation (328). Small PA size, PVR >4 wood units, preoperative PA pressure >15 mm Hg, or the presence of venovenous collaterals constitute a high-risk group of patients (326,329). In addition, more complex anatomy that requires main PA to ascending aorta anastomoses or ventricular septal defect enlargement, both indicators of ventricular outflow obstruction, has been identified as a risk factor for late morbidity.

Ventricular Dysfunction

Volume unloading provided by staged palliation results in reduction in ventricular size and wall thickness that, in turn, increases contractility and ventricular performance. Ventricular dilation, however, may persist in some patients due to early volume overload, as well the presence of aortopulmonary collaterals that are common in patients with chronic cyanosis. Regardless of the early success with staged palliation, late ventricular dysfunction after the Fontan operation may ensue due to morphologic/structural features of the single right systemic ventricle, residual obstructive lesions, and/or atrioventricular valve insufficiency. The failing systemic ventricle after staged palliation can be attributed to systolic dysfunction, diastolic dysfunction, or both (329–332). Systolic dysfunction is characterized by reduced contractility and an ejection fraction of <50%. Diastolic dysfunction is more difficult to define, but is evident by increased ventricular end-diastolic pressure and the rate of ventricular relaxation (333,334). As a result, late ventricular dysfunction and subsequent failure of Fontan circulation become clinically evident with symptoms of lower functional class, exercise intolerance, dyspnea, fatigue, and syncope (335, 336).

Hypoxemia

Slight hypoxemia with SaO_2 in the low 90s is common after Fontan completion even when residual atrial-level shunts (fenestrations) are absent (321,328). This desaturation is thought to result from coronary sinus blood return to the pulmonary venous atrium, and/or ventilation/perfusion imbalances within the lung. Desaturation also commonly occurs in patients with residual anatomic shunts such as a persistent atrial-level shunt (fenestration) or acquired collateral circulation within the lung.

In a study by Friedman et al. in which the prevalence and risk factors for aortopulmonary collateral vessels were assessed, collateral vessels were present in over 1/3 of patients who underwent either a bidirectional Glenn or Fontan procedure, and was most prevalent in patients with a history of a Blalock-Thomas-Taussig shunt. Most collateral vessels originated from the internal mammary arteries and thyrocervical trunk with fewer vessels originating from the brachiocephalic vessels (337). Admittedly, aortopulmonary collaterals should not cause hypoxemia but can result in volume overloading of the single RV.

Venovenous collaterals that drain directly into the LA or pulmonary venous circulation can also serve as a source of arterial desaturation after Fontan palliation. The collateral circulation that forms after Fontan palliation plays no role in gas exchange, produces right-to-left intrapulmonary shunts, and might contribute to progressive ventricular dysfunction as a source of chronic volume overload (338). Hence, the impact of intrapulmonary collateral circulation on oxygen saturation is variable but often most pronounced in the presence of progressive ventricular dysfunction.

Protein-Losing Enteropathy

PLE, a phenomenon of hypoalbuminemia through intestinal protein loss, occurs with an incidence of 3% to 15% in patients with Fontan circulation and has a reported mortality of 30% at 2 years and 50% at 5 years after diagnosis (339–341). Onset of PLE can be as early as 1 month to nearly two decades after Fontan palliation but occurs most commonly two to three years following the Fontan procedure (342).

The pathogenesis of PLE remains elusive despite increased understanding of univentricular physiology. Chronically elevated systemic venous/right atrial pressures with subsequent increased IVC and portal vein pressures have been implicated

as the primary cause of PLE. This elevation in abdominal venous pressures presumably leads to intestinal congestion, lymphatic obstruction, and enteric protein loss (342). Diastolic dysfunction, as mentioned previously, that results in low cardiac output in the face of elevated venous pressures, or even with venous pressures considered normal for Fontan physiology (<15 mm Hg), predisposes the patient to mesenteric ischemia and subsequent intestinal mucosal injury leading to the onset of enteric protein losses (328,342). Finally, inflammation due to infection or unexplained etiologies can result in epithelial membrane injury that may result in PLE despite the absence of hemodynamic derangements (343–346).

In a large retrospective multicenter study which included >3,000 patients with Fontan circulation in whom the incidence of PLE was 3.7%, ventricular anatomy other than dominant LV and an elevated preoperative ventricular end-diastolic pressure were risk factors for the development of PLE (342). Other large single-center studies have confirmed these findings, but also identified heterotaxy, polysplenia, anomalies of systemic venous drainage, increased pulmonary arteriolar resistance, and longer CPB time at Fontan palliation as risk factors for the development of PLE (328,339,340).

It has been agreed that PLE is poorly understood in its etiology and that it may occur from weeks to years after the Fontan operation. Rychik and Spray (341) suggested that an increase in mesenteric artery resistance after the Fontan operation, with a concomitant decrease in mesenteric artery blood flow, was associated with PLE. The clinical manifestations of PLE vary widely and the multiple potential therapies include diuretic use including aldactone and chlorothiazide, supplemental protein administration, attempts at minimizing intestinal protein loss with steroids and heparin, and altering the cardiovascular physiology with fenestration creation. If the above therapies prove unsuccessful, cardiac transplantation can be offered.

Thacker et al. (347) recently reported on the use of budesonide, a steroid with a high enteric anti-inflammatory effect, in the management of PLE after the Fontan operation. They suggested that budesonide resulted in an improvement of serum albumin within 6 months and that low-dose therapy must be continued in order to result in a sustained effect.

Finally, Bernstein et al. (348), in a retrospective multi-institutional review reported the results of cardiac transplantation in the therapy of failing Fontan patients, many of whom had PLE. Although the survival for this group of patients was slightly less (1 year 76%, 3 years 70%, 5 years 68%) than those patients with congenital heart disease, but without a Fontan, and those patients without congenital heart disease, the long-term results were encouraging and all surviving patients who had PLE had eventual resolution of PLE. Specifically, PLE was present in 34 of the 97 Fontan patients in this study and complete resolution of PLE was noted in all who survived >30 days after transplantation.

Thromboembolism

Patients with Fontan circulation have a lifelong risk of thromboembolic complications, particularly stroke and pulmonary embolism. In a large series by Coon, the reported prevalence of thrombus formation as detected by transthoracic echocardiography was 8.8% with the majority of thrombi detected within the first year of Fontan palliation (mean age 2.3 months, range 1 day to 163 months) (349). In smaller series, the diagnosis of thrombus formation was more common with transesophageal echo with a reported prevalence of 17% to 30% (350). The high rate of thrombus formation is postulated to be predominately secondary to venous stasis and impaired cardiac output that is inherent to single-ventricle circulation. No difference has been observed in patients who received a lateral

tunnel or atriopulmonary Fontan (349). Several studies report the presence of arrhythmias at the time of thrombus detection (349–352). Finally, liver dysfunction and coagulation factor deficiency, particularly protein C deficiency, have been identified in patients thought to have good outcomes after the Fontan operation; however, they appear to be time-related phenomena that resolve over time (353,354). The optimal anticoagulation regimen for the patient after the Fontan operation is still unclear and is the subject of current ongoing investigation.

Arrhythmias

Late atrial arrhythmias have a reported incidence of 10% to 5% in patients with Fontan physiology (326,328,334,335,355). Sinus node dysfunction, the presence of atrial suture lines, and increased atrial pressure have all been implicated in the etiology of late arrhythmias. In recent years, the surgical approach for the Fontan has been modified from the lateral tunnel to the extracardiac Fontan with the goal of reducing the incidence of atrial arrhythmias. The extracardiac Fontan has theoretic advantages in achieving this objective as this approach minimizes atrial suture lines and lessens the atrial hypertension that is expected with the lateral tunnel Fontan. Several series have reported this outcome with a decreased incidence of atrial tachyarrhythmias or pacemaker insertion for sinus node dysfunction in patients who underwent the extracardiac Fontan when compared to those patients subjected to the lateral tunnel Fontan (312,356,357). Conversely, Cohen reported no early benefit with either approach early after the Fontan operation (314).

Cardiac Transplantation

Primary Transplantation

In the past, some centers have chosen cardiac transplantation as the preferred primary therapeutic approach to HLHS (358–369). Bailey has reported the results of neonatal transplantation for HLHS. Between 1985 and 1996, 176 infants with HLHS were listed for cardiac transplantation. Nineteen percent of this group died prior to the identification of a donor heart. One-hundred and forty-two patients underwent transplantation between 1.5 hours and 6 months of life (median 29 days). Actuarial survival of patients who underwent transplant at 1 month, 1, 5, and 7 years was 91%, 84%, 76%, and 70%, respectively. This actuarial survival did not take into account the group of patients that died prior to an available donor heart. Intermediate-term follow-up of this group of patients has shown good growth and development (360). Evidence of neurodevelopmental delay has been noted in 11%, with normal psychomotor development in 91% and a normal developmental index in 96% (360,370).

Donor availability continues to be a limiting factor to primary transplantation with the donor shortage resulting in 25% to 30% mortality while on the waiting list. Alternative strategies to reduce pretransplant mortality include ABO incompatible neonatal transplantation. West has demonstrated promising results in patients who underwent ABO-incompatible transplantation with a concomitant decrease in mortality in those patients awaiting primary transplantation (371,372).

Transplant for Failed Palliation

Cardiac transplantation has been used at most centers for patients with HLHS who have failed or are poor candidates for staged palliation. Indications include severe, symptomatic right ventricular dysfunction and/or tricuspid valve regurgitation at any stage of repair. In addition, cardiac transplantation should be considered for the patient with severe, intractable PLE that is refractory to the usual therapeutic maneuvers,

occasionally seen after the completion Fontan operation. Transplantation required in the course of staged palliation may be complicated by immunologic sensitization as a result of previous surgical interventions and the inherent need for blood transfusion. In the past, this sensitization required prospective cross-matching of the donor and recipient in order to find a suitable donor. Currently, the availability and use of the virtual cross-matching technique (373) has eliminated the need for prospective cross-matching. This technique (374) can lead to shorter wait times and better outcomes as a listing strategy for the group of sensitized patients. In addition, although the sensitized group of patients may have a higher risk of antibody-mediated rejection after transplantation, this also can be monitored carefully post-transplantation by vigilant surveillance for the potential development of donor-directed antibodies and by the rapid and early intervention for antibody-mediated rejection if necessary.

Several centers have reported their results for heart transplantation in patients with previous Fontan operations. Gamba reviewed results from 1990 to 2002 in 14 patients who underwent heart transplantation after a previous Fontan operation. The mean age at the time of Fontan was 7.3 ± 2.8 years with the mean age at transplantation of 17.2 ± 6.3 years. The indication for transplantation was PLE in 7 patients, arrhythmia with ventricular dysfunction in five patients, and heart failure in two patients. Late survival was reported in 10 patients at a mean follow-up of 64 ± 42 months with patients in New York Heart Association class I category (375).

Michielon evaluated the incremental risk factors for early mortality after heart transplantation. Between 1988 and 2002, 25 patients underwent heart transplantation 15 of whom had a functional RV and 10 of whom had a functional LV. Twenty-two patients (88%) had received a previous completion Fontan operation. Transition to heart transplantation occurred from a shunt in 10 patients, a bidirectional cavopulmonary anastomosis in nine patients, and after Fontan failure in six patients. Overall 30-day survival was 68% with no additional mortality up to 14.1 years. Heart transplantation following bidirectional cavopulmonary anastomosis exhibited 100% long-term survival as opposed to 68% after systemic-to-PA shunt and 33% following the failing Fontan circulation. Michielon concluded that heart transplantation for patients with single-ventricle physiology is associated with substantial early mortality while the bidirectional cavopulmonary anastomosis provides the best transition to heart transplantation (376).

Bernstein's review of the outcomes of cardiac transplantation was noted earlier in the discussion of PLE (348). In this study, it should be noted that risk factors for death while waiting for cardiac transplantation included a young age, status 1 listing, shorter interval since the Fontan operation, and the need for mechanical ventilation.

Neurodevelopmental Outcomes and Quality of Life

Relative to other forms of congenital heart disease, the diagnosis of HLHS may impose one of the highest risks of neurodevelopmental and behavioral abnormalities for survivors. Neurologic outcomes are influenced by patient-related factors as well as preoperative, perioperative, and long-term risk factors. The collective effect of the multiple risks faced by children with HLHS results in a complex, multifaceted impact on development (377).

There are several factors that may impact neurodevelopment that are not readily modifiable such as congenital brain anomalies or abnormal fetal brain development (16,378–381); genetic syndromes, polymorphisms, and other comorbid conditions (25,382–384); prenatal versus postnatal diagnosis (385); and socioeconomic status or parental intelligence

(270,386,387). These must be taken into consideration when counseling parents or investigating the causes of an identified delay.

Recently implemented strategic approaches to care for infants and children with HLHS including improvements in hemodynamic stability before, during, and after surgery (175,177,183,290,388,389), perioperative neuroprotection (189,269,390), reduction of seizures and embolic events (391,392), and the effects of CPB (393,394) are anticipated to result in a reduction of cumulative neurologic risk. Treatment modalities for HLHS have evolved dramatically in a relatively short period of time making it difficult to generalize conclusions from historical cohorts to current patients. It is hoped that today's vastly improved understanding of the physiology of HLHS, optimal treatment choices, and reduction of the overall profile of risk for these patients will result in improved long-term neurodevelopmental outcomes for infants with HLHS born today.

Early studies of neurodevelopmental outcomes in children with HLHS demonstrated major delays in multiple areas of functioning and raised awareness of the importance of long-term monitoring in this population (395,396). More recently, research has demonstrated that children with HLHS often demonstrate overall IQ within the low range of normal but that they manifest important delays in visual-motor integration, executive functioning, and motor development as well as a higher than expected incidence of behavioral abnormalities, particularly attention deficits (382,387,397–401). IQ alone does not fully represent the spectrum of outcomes in this patient group, increasing the importance of comprehensive neuropsychological and behavioral follow-up. Routine developmental screening, beginning at 6 months of age in infants with complex heart disease has been shown to be useful in identifying patients who would benefit from early intervention therapy to reduce delays (402).

A range of outcomes for children with HLHS has been reported in the literature. The majority of parents (79%) of 115 school-aged children with HLHS rated their child's health as good to excellent (397). Eighty-eight percent reported minimal activity limitations and 84% rated school performance as average or above-average. Despite these encouraging parental perceptions, one-third of these children were receiving special education services. In the 28 children who underwent standardized developmental testing, the median full scale IQ was 86 with 18% of subjects demonstrating mental retardation ($IQ < 70$). The subjects in this study were all born prior to 1992 with a mean age of 9 ± 2.1 years at the time of study completion.

In 51 patients with Fontan physiology who underwent testing at a mean age of 4.8 ± 0.4 years, neurodevelopmental and behavioral outcomes were found to be within the normal range. However, children with HLHS demonstrated lower scores for overall, verbal and performance IQ than non-HLHS patients (93.8, 98.9, and 89.7 vs. 107, 110, and 101.9, respectively) (387). Scores for adaptive behavior and behavior problems did not differ between HLHS and non-HLHS subgroups. Very similar neurodevelopmental outcomes were reported for 26 children with HLHS who were treated with cardiac transplantation between 1993 and 1998 and tested at age 1.9 to 6.6 years (370). In this study, subjects had a median overall IQ of 89. Longer waiting time prior to transplantation was found to have a negative effect on later neurocognitive outcomes. These findings were subsequently confirmed in a multicenter study (401). Surgical approach, staged palliation versus transplantation, was not associated with any measure of developmental outcome in a group of 47 school-aged children representing four institutions. For the entire cohort, mean full-scale IQ was 86 ± 14 . Lower full-scale IQ, verbal, and math performance were associated with longer hospital stay at the

time of initial surgery. Wernovsky and Newburger (403) postulated that these similar findings, despite dramatically different treatment strategies, are evidence of the important impact of genetic factors, congenital brain abnormalities and insults incurred during the pre- and perioperative period. These risks are present despite the treatment method chosen.

In the Pediatric Heart Network cross-sectional study of 537 Fontan survivors at 6 to 18 years of age, parents reported problems with attention in 46%, learning in 43%, development in 24%, and behavior in 23% (398) demonstrating the wide spectrum of neurologic impact of complex heart disease. Operative factors have been the most widely studied and most significantly modified factors in an attempt to minimize intraoperative neurologic injury. However, operative factors typically only account for a small portion of the variance in outcomes (241,393,394,404,405). In a recent cohort of 88 patients with HLHS evaluated at 1 year of age, mental and psychomotor development was significantly lower than norms (382). The median Mental Development Index (MDI) was 90 with 11% of patients scoring greater than two standard deviations below the population mean (<70). The median Psychomotor Development Index (PDI) was 73 and 48% of the sample had scores of <70 . Motor delays are significantly more common than mental delays in all samples of infants with HLHS. Genetic abnormalities, lower gestational age, and the need for preoperative intubation were significant predictors of 1-year outcomes whereas operative variables, including duration of DHCA, were not.

Similarly, children undergoing surgery with DHCA versus continuous cerebral perfusion did not demonstrate differences in developmental outcomes at 1 year of age in a single institution randomized trial of perfusion techniques (270). In this cohort, the mean MDI was 92 and mean PDI was 77; however, as previously noted, the continuous cerebral perfusion flow rate in this trial was not likely high enough to meet brain metabolic demands. Children between 4 and 5 years of age with HLHS had significantly lower scores for cognition, fine motor skills, executive function, and math skills than children with transposition of the great arteries, tetralogy of Fallot, or ventricular septal defect. However, the mean scores for each domain were within normal limits for all groups (406). Perioperative risk has also been explored. A significant relationship between SVC SvO₂ in the first 48 hours following the Norwood procedure and developmental and behavioral outcomes in children with HLHS assessed at 4.5 years of age has been demonstrated (290). Postoperative SvO₂ values $<40\%$ were independently associated with poorer developmental outcomes. In a multivariable model, SvO₂, circulatory arrest time, CO₂ tension, and mean arterial blood pressure accounted for 79% of the variation in the developmental outcomes assessed; thus avoidance of conditions contributing to early cerebral hypoxia were associated with improved neurodevelopmental outcome (see Fig. 48.25).

These studies have evaluated children at multiple different ages and stages of repair. Generalization to today's child undergoing care for HLHS is difficult; however, these preliminary data emphasize the need for comprehensive follow-up and evaluation of developmental progress for these subjects. Further multicenter research involving thorough longitudinal assessment of children with HLHS is needed to understand neurodevelopmental risks and to optimize outcomes for these children. Several important studies including those of the Pediatric Heart Network, the Congenital Heart Surgeons Society, the Pediatric Heart Transplant Study Group, and individual investigators are carefully examining outcomes for the modern cohort of children with HLHS. Their findings will serve as a guide for future care and provide important information for counseling children, families, educators, and other health care practitioners.

FIGURE 48.25. Neurodevelopmental outcome, as a composite of scores from four tests at 4 years of age, as a function of SVC SvO₂ in the 48 hours following the Norwood procedure. Reduced performance in this cohort was associated with SvO₂ <40%. ANOVA, analysis of variance; CI, confidence intervals; SvO₂ systemic venous oxygen saturation. (Reprinted from Hoffman GM, Mussatto KA, Brosig CS, et al. Systemic venous oxygen saturation after the Norwood procedure and childhood neurodevelopmental outcome. *J Thorac Cardiovasc Surg* 2005;130:1094–1100, with permission from Elsevier.)

The intensive focus on improving outcomes for children with HLHS has allowed us to begin to look beyond survival at the long-term psychosocial implications of this complex congenital heart disease. In 2010, a survey of 749 pediatric cardiologists and surgeons found that 99.7% discussed staged palliative surgery, 67% discussed cardiac transplantation and 62% discussed comfort care without surgery. Only 15% reported offering all of these options to families (407). The lack of long-term outcome data on quality of life (QOL) for survivors with HLHS is one of the major reasons for the continued debate about the applicability of a “no treatment” option and a variety of approaches to treatment decision making (407–410). While there is much yet to be learned, there is increasing awareness about QOL, functional outcomes, and impact on the family in children living with HLHS.

Children and families living with HLHS experience both physical and psychosocial challenges including uncertainty about long-term prognosis, chronic medication use, persistent symptoms, the prospect of developmental delay, and the need for repeated interventions. It would be inappropriate to propose that the combination of these factors has no impact on QOL. However, it is equally wrong to assume that bad outcomes are inevitable. QOL is a highly subjective, multidimensional concept that includes not only the impact of disease but also personal perceptions, expectations, satisfaction, and other factors (411,412). Although cultural differences in approaches to care for HLHS exist (413), health care professionals universally hope that patients realize “quality” of life versus “quantity” alone. The definition of quality, however, can be provided only by the children and families living the experience. It has been demonstrated repeatedly in congenital heart disease and other pediatric chronic illnesses that severity of illness is not a reliable predictor of QOL (414–417). It cannot be assumed that children with HLHS will experience a poor QOL.

Access to large cohorts of survivors of HLHS has been limited; therefore, few studies have examined psychosocial outcomes in this population exclusively. However, several studies have addressed these outcomes in groups representing

survivors of a variety of forms of single-ventricle heart disease. In studies by Casey et al. (418,419) of 26 children with various forms of single-ventricle lesions, it was found that 80% of parents underestimated the exercise tolerance of their children. Parents reported that their children had more social problems and decreased activities, and were more withdrawn than healthy children. Teachers also reported children with single-ventricle heart disease to be more withdrawn in the classroom setting. Sixty-five percent of these children attended school full-time, and 27% attended half-time or more. School adjustment in the children was found to be significantly related to both family strain and exercise tolerance. The impact of the child’s chronic condition on the family appeared to be a more important predictor of behavioral adjustment than the symptoms the children experienced. In another study, adults with single-ventricle heart disease ranging in age from 17 to 49 years reported QOL that was similar to healthy controls. Younger patients in the sample reported better overall QOL (420).

In a cross-sectional evaluation of the impact of HLHS in children at various stages of surgical palliation operated in the 1990s, QOL was rated as normal after stage 1 surgery; however, the lowest QOL reports were in children following stage 2 palliation (421). QOL was not related to the degree of developmental delay identified. However, longer circulatory arrest times were found to have a negative impact on QOL indicators. The authors speculated that differences in parental expectations during early childhood may account for these different responses. Parents reported lower self-esteem, more psychosomatic symptoms, and lower peer acceptance in a small cohort of 18 children with HLHS born between 1993 and 2005 and assessed at 2.7 to 10.6 years of age compared to age and gender-matched healthy children (422). There was also a higher rate of separation and divorces in the families of children with HLHS.

The Pediatric Heart Network reported outcomes of a cross-sectional study of 537 children with Fontan physiology in which QOL, heart rhythm, exercise tolerance, and data on other physical morbidities were collected (398,423,424). It was theorized that QOL may provide a proxy indicator of physical function. The study identified scores for quality of physical health that were approximately one standard deviation below normal and scores for psychosocial health that were one-half standard deviation lower than normative values for the Child Health Questionnaire. In the majority of health status domains, parents reported worse physical and psychosocial function than children reported for themselves (425). QOL in these Fontan survivors was less than that of healthy children; however, perceptions of QOL were influenced by multiple factors including socioeconomic status and the presence of other comorbid conditions, not only those related to cardiac outcomes. These findings once again emphasize the inherent disconnect between physiologic variables and subjective variables such as QOL.

For the first time in history, large cohorts of children with HLHS are developing into adolescents and young adults. This generation of children has benefited from numerous strategies to optimize neuroprotection and to support healthy psychosocial development. Further prospective, longitudinal research on neurodevelopmental and QOL outcomes, and their determinants, is needed to understand the impact of this disease. Strategies to help adolescents and young adults with HLHS achieve their full potential should be incorporated into our routine clinical surveillance and care. In December 2010, an interview with a 25-year-old survivor of HLHS aired on National Public Radio (426). Despite some physical limitations, the interviewer commented, “She seems to thrive within the context of her life.” This should be our goal for every patient with HLHS.

SUMMARY

The ventricle is a remarkably preserved structure throughout vertebrate evolution and is the workhorse of the circulation. The fundamental problem of an inadequate power supply remains the primary problem for those caring for the newborn with HLHS and persists throughout life. Although the early and intermediate outcomes in terms of survival have improved over the last decade, considerable challenges remain including options for the failing circulation, optimizing long-term neurodevelopmental outcome, and justifying allocation of increasingly scarce health care resources to a complex group of patients. Ongoing research provides hope for the future. Short-term goals include identification of the causes of HLHS to decrease the incidence, improvements in fetal intervention to improve the outcome for those born with HLHS, and improved medical, mechanical, and transplant strategies for treatment of the failing circulation to improve survival and QOL of affected individuals.

ACKNOWLEDGMENTS

The authors wish to thank Mara Koffarnus for her tireless and invaluable assistance in preparing this chapter.

Gil Wernovsky

Transposition of the great arteries (TGA) is a lethal and relatively frequent malformation, accounting for 5% to 7% of all congenital cardiac malformations. Without treatment, about 30% of these infants die in the first week of life, 50% within the first month, 70% within 6 months, and 90% within the first year (Fig. 49.1). Today, aggressive medical and surgical interventions in the neonate can provide >90% early and midterm survival and, for many patients, the prospect of a vigorous adolescent and adult life.

The incidence is reported to range from 20.1 to 30.5/100,000 live births with a strong (60% to 70%) male preponderance. Although earlier epidemiologic and genetic surveys suggested some other associations, for example, increased prevalence in infants of diabetic mothers or prenatal exposure to sex-hormone therapy, these have not been confirmed. Extracardiac anomalies are less frequent in infants with TGA (<10%) compared with other forms of congenital heart disease, such as truncus arteriosus (48%), ventricular septal defect (VSD) (34%), or tetralogy of Fallot (31%).

ANATOMY AND PATHOLOGY

Nomenclature

Anatomists, surgeons, and cardiologists have chosen a variety of terms to describe the basic anatomic abnormality in transposition: the aorta arising from a morphologically right ventricle and the pulmonary artery arising from a morphologically left ventricle (Fig. 49.2). The great arteries may be related normally or abnormally to each other, to the ventricles, to the ventricular septum, and to the atrioventricular (AV) valves. Normally and abnormally related great arteries customarily are designated in terms of their ventriculoarterial connections or alignments, that is, normal, transposed, double-outlet right or left ventricle, and anatomically corrected malposition.

The common clinical type, that is, with situs solitus of the atria, concordant AV (right atrium to right ventricle and left atrium to left ventricle), and discordant ventriculoarterial alignments, is widely termed complete TGA. The modifying term complete by present classification and nomenclature is redundant; however, it has, by common usage, come to indicate that the transposed great arteries are physiologically uncorrected, that is, that systemic venous blood flows predominantly to the aorta and pulmonary venous blood to the pulmonary artery. In this usage, the term complete is contrasted to the term corrected, as in corrected TGA (i.e., physiologically corrected), in

which systemic venous blood flows to the pulmonary artery and pulmonary venous blood to the aorta. It should be recognized, however, that both the physiologically uncorrected and physiologically corrected transposition hearts are morphologically complete transpositions; that is, both great arteries are completely (or predominantly) misplaced across the ventricular septum and arise from morphologically inappropriate ventricles and thus have discordant ventriculoarterial connections.

Using the segmental (atria, ventricles, arteries) approach and the situs-independent dextro-(D) and levo-(L) denotations favored by Van Praagh, the clinical material in this chapter concerns almost exclusively TGA {S,D,D}, that is, TGA with situs solitus (S) of the atria and viscera, usual (D) looping of the ventricles, and an anterior and rightward (D) aorta. If the transposed aorta at the valve annulus level is positioned to the left of the transposed pulmonary artery, the malformation may be denoted as TGA {S,D,L}. A rare type of transposition has been described with the aorta posteriorly positioned but nevertheless aligned with and connected to the anterior morphologically right ventricle. An additional modifying term, simple, has been used by some morphologists to exclude hearts with transposition that have additional associated malformations such as AV valve atresia or straddling, common AV orifice, or single-ventricle hearts with small outlet chambers. This chapter is concerned primarily with the category of simple transposition and includes TGA with intact ventricular septum (IVS), VSD, patent ductus arteriosus (PDA), and left ventricular outflow tract obstruction (LVOTO), in all, a group comprising about 80% of patients with TGA. In addition, double-outlet right ventricle (DORV) with subpulmonary VSD (considered within the spectrum of Taussig-Bing anomaly) is also discussed here because it has some of the morphologic features, similar physiology, and all the surgical options that pertain to TGA with large subpulmonary VSD. It is important to note that many surgical and clinical reports use this same term, simple TGA, to designate the large important subgroup of TGA patients with IVS (or extremely small VSD) but without any other significant associated lesion (thus excluding TGA with large VSD, large PDA, and significant LVOTO).

Morphogenesis and Etiology

The detailed developmental aspects of abnormal ventriculoarterial relationships remain largely unknown; however, abnormal development, growth, and absorption of the distal infundibulum (conus) are considered by some major factors. Recent work with more modern genome-wide array testing

Figure 49.1. Survival of patients with TGA. Lall and Livs represent “natural history” survival data on 742 patients from 1957 through 1964 antedating both Mustard repair and BAS. (Data from Liebman J, Cullum L, Belloc NB. Natural history of transposition of the great arteries: anatomy and birth and death characteristics. *Circulation* 1969;40:237–262.) Lall represents all TGA subtypes, and Livs represents only patients with TGA/IVS. T1 represents 20-year actuarial survival of 106 infants with TGA/IVS following Mustard repair performed from 1963 through 1973; T2 represents 12-year actuarial survival of 223 children following Mustard repair performed from 1974 through 1985. (Data from Trusler GA, Castaneda AR, Rosenthal A, et al.; Congenital Heart Surgeons Society. Current results of management in transposition of the great arteries, with special emphasis on patients with associated ventricular septal defect. *J Am Coll Cardiol* 1987;10:1061–1071.) K represents risk-adjusted probability of survival after an arterial switch repair in a neonate with TGA/IVS or TGA/VSD as observed in a study conducted by the Congenital Heart Surgeons Society from 1985 through 1989 on 513 patients undergoing the arterial switch operation. (Data from Kirklin JW, Blackstone EH, Tchervenkov CI, et al.; Congenital Heart Surgeons Society. Clinical outcomes after the arterial switch operation for transposition: patient, support, procedural and institutional risk factors. *Circulation* 1992;86:1501–1515.) Risk-adjustment conditions included neonate operated on in an institution of proven competence (“low-risk” institutions, $n = 7$), “usual” TGA coronary artery pattern, single VSD, absence of coexisting noncardiac anomalies, and average birth weight.

shows early promise in detecting a genetic etiology in some, particularly mutations in the laterality genes in the spectrum of heterotaxy syndrome (1).

The normal conus is subpulmonary, left sided, and anterior, and it prevents fibrous continuity between the pulmonary and tricuspid valve rings. In TGA, the infundibulum is usually subaortic, right sided, and anterior, and it prevents fibrous continuity between the aortic and tricuspid valve rings (Fig. 49.3B). It has been noted in human embryos that normal movement of the pulmonary valve proceeds from posterior to anterior on the left side in the interval between 30 and 34 days of age and is related to normal development of the subpulmonary infundibulum. During this same interval, the aortic valve remains stationary, apparently because of the normal lack of development (or absorption) of the subaortic infundibulum. The morphogenesis of TGA can be hypothesized to result from the abnormal growth and development of the subaortic infundibulum and the absence of growth of the subpulmonary infundibulum. The aortic valve is protruded superiorly and anteriorly by the development of the subaortic infundibulum, placing it above the anterior right ventricle (Fig. 49.3). Failure of development of the subpulmonary infundibulum prevents the normal morphogenetic movement of the pulmonary valve from posterior to anterior and further results in abnormal pulmonary to mitral valve ring fibrous continuity. Pasquini et al. (2) demonstrated considerable variation in the conal anatomy of hearts with TGA.

Cardiac Segments

Usually, the atria are formed normally, with normal internal anatomy. Almost always, there is a patent foramen ovale and only rarely (5%) a true secundum atrial septal defect (ASD). Consistent with the normal atrial anatomy, the sinus and AV nodes are in their usual locations. Specialized tracts of conduction tissue between the nodes have not been conclusively demonstrated; however, surgical damage to the crista terminalis or superior rim of the fossa ovale may be important in the genesis of supraventricular dysrhythmias frequently noted after atrial inversion procedures.

The right ventricle is normally positioned and becomes progressively hypertrophied and enlarged in the uncorrected patient and in patients following Mustard or Senning repairs. The inflow and sinus portions are essentially normal in architecture, but the central fibrous body is abbreviated and the AV and membranous interventricular septa are smaller than normal. With IVS, the entire septum is usually a relatively straight structure and does

Figure 49.2. Complete TGA. A: Angiocardiogram (left anterior oblique view). B: Two-dimensional echocardiogram (subcostal view) showing discordant ventriculoarterial alignments. Right-sided (anterior) aorta (AO) connected to right-sided (anterior) morphologically right ventricle (RV) and left-sided (posterior) pulmonary artery (PA) connected to left-sided (posterior) morphologically left ventricle (LV).

Figure 49.3. Morphology in typical TGA. **A:** Anterior view of right ventricle (RV): aorta (AO) arising anterior and to the right of pulmonary artery (PA) and left anterior descending coronary artery (LAD), which arises from the left posterior “facing” sinus of Valsalva. LAA, left atrial appendage; LV, left ventricle; RA, right atrium. **B:** Interior view of right ventricle with prominent subaortic conus (C). Arrows embracing C delineate prominent muscle bar composed of portions of right ventriculoinfundibular fold (parietal band), infundibular septum, and rightward extension of trabecular septomarginalis (septal band) musculature. AV, aortic valve; SB, septal band; TV, tricuspid valve.

not have the sigmoid curvature typical of the normal heart; consequently, the right ventricular outflow tract runs parallel to the left ventricular outflow tract (LVOT) (Fig. 49.2). Almost always, when the ventricular septum is intact, there is a subaortic conus separating the aortic valve from the tricuspid valve (Fig. 49.3B), whereas the pulmonary valve is in fibrous continuity with the mitral valve (Fig. 49.4A). The outlet (infundibular) septum joins normally with the ventricular septum between the limbs of the trabecula septomarginalis (septal band). The infundibulum projects directly superiorly to the aorta from the sinus portion of the ventricle rather than superiorly, anteriorly, and leftward to the pulmonary artery as in the normal heart.

In the left ventricle, there is usually pulmonary–mitral fibrous continuity comparable to the aortic–mitral continuity present in the normal heart (Figs. 49.4 and 49.5). Left ventricular posterior wall thickness and cavity shape are dependent on age and the presence of associated lesions (VSD, PDA, LVOTO), and are of major importance when considering arterial switch surgery.

The aortic position is the most obvious external abnormality that manifests in TGA. In most patients with situs solitus

and IVS, the aortic root is directly anterior or anterior and to the right of the pulmonary trunk in a slightly oblique relationship (Fig. 49.6). Less commonly, the aorta may be positioned anterior and to the left or, rarely, posterior and to the right of the pulmonary trunk.

Until recently, the extensive anatomic variability of the coronary arteries in hearts with TGA was of academic interest only. Shafer and Puddu described the multiple variations in the origin and epicardial course of the coronary arteries as early as 1966. This marked diversity has been confirmed in other pathologic and surgical series (3–5). In normally related great arteries, the fixed interrelationship between the aorta and pulmonary trunk minimizes the abnormalities of the origin and distribution of the coronary arteries. The variable interrelationship of the aorta and pulmonary trunk in TGA, however, as well as the variability in the size and orientation of the conal septum probably account for the greater variation in the origin and distribution of the epicardial coronary arteries in TGA. The coronary arteries appear to take the “shortest route” to a sinus in the aortic root. For example, when the aorta is more

Figure 49.4. Septal bulge in TGA. **A:** Autopsy specimen from 2-year-old patient showing prominent convex bulging (arrows) of interventricular septum toward left ventricular (LV) cavity. Catheterization revealed a peak systolic left ventricular outflow tract pressure gradient of 58 mm Hg. Note mitral valve (MV) to pulmonary valve (PV) fibrous continuity and the absence of any discrete fibromuscular ridge at the septal impact site of the mitral valve. **B:** Superimposed systolic and diastolic angiographic frames from 4-year-old patient 2 years after intra-atrial repair illustrating abnormally prominent posterior septal bulging into the left ventricular cavity during systole. No localized fibromuscular ridge stenosis was visualized. Pressures were LV apex, 60/8; LV outflow, 24/8; and pulmonary artery (PA), 24/18 mm Hg.

Figure 49.5. A,B: Left ventricular (LV) angiocardiograms (frontal view) in a patient with TGA/IVS illustrating development and progression of LVOTO. A: At 2 days of age, no angiographic evidence of LVOTO; pressures were right ventricle (RV), 70/7 mm Hg; LV, 35/5 mm Hg. B: Same patient at 4 months of age when selective LV angiogram demonstrated prominent subpulmonary fibromuscular ridge causing LVOTO; pressures were RV, 80/6 mm Hg; LV, 80/6 mm Hg; and pulmonary artery (PA), 14/10 mm Hg. MV, mitral valve; S, obstructive subpulmonary fibromuscular ridge. Arrows indicate pulmonary valve leaflets. C,D: Autopsy specimens illustrating LVOT with fibromuscular ridge pathology (arrows). Note the relationship of the mitral valve (MV) impact region to site of ridge. C: Pathologic specimen, early fibromuscular ridge in 2-month-old infant. D: Pathologic specimen, moderately severe fibromuscular ridge obstruction in 2-year-old patient with peak systolic pressure gradient of 64 mm Hg across LVOT. PV, pulmonary valve.

Figure 49.6. Nomenclature of the aortic sinuses that contain the coronary ostia, based on the interrelationship of the great arteries. Ant, anterior; Ao, aorta; Inf, inferior; PA, pulmonary artery; Post, posterior; Sup, superior. (Modified from Wernovsky G, Sanders SP. Coronary artery anatomy and transposition of the great arteries. *Coron Artery Dis* 1993;4:148–157, with permission.)

posterior (as in side-by-side great arteries), the circumflex coronary artery or even the entire left coronary artery system may arise from the posterior facing sinus, whereas the right coronary artery arises from the aorta anteriorly, a distribution similar to normally related great arteries.

The two aortic sinuses of Valsalva adjacent to the aorticopulmonary septum that “face” the pulmonary artery contain the ostia of the coronary arteries in more than 99% of cases; these are termed the septal or facing sinuses. When the great arteries are directly anterior–posterior, the facing sinuses are directed leftward and rightward. When the great arteries are directly side-by-side, the facing sinuses are directed anteriorly and posteriorly. When the aorta is anterior to and rightward of the pulmonary artery (the typical interrelationship), the facing sinuses are leftward/anterior and rightward/posterior (Fig. 49.6). Alternative classification systems label the septal or facing sinuses with arbitrary numbers (e.g., sinus 1 and sinus 2) (6) or letters (3), whereas others have suggested labeling the facing sinuses right or left, but as it relates to the surgeon’s hands rather than the patient’s anatomy (7). Although this labeling might be a helpful distinction during surgery, it is certainly not standard anatomic practice (the anatomically right ventricle is not considered to be the left ventricle when the surgeon is operating on it).

As in hearts with normally related great arteries, the three major coronary arteries are (a) the right coronary artery, defined as the coronary artery that passes in the right AV groove; (b) the circumflex coronary artery, defined as the coronary artery that passes in the left AV groove; and (c) the left anterior descending artery, the coronary artery that parallels the interventricular septum on the anterior surface of the heart. In addition, the proximal portion of each of the three major branches may pursue an intramural course, usually between the two great vessels. In these cases, the media of the aortic and coronary walls are attached without interposed adventitia. Thus, given the two sinuses of origin, three major branches, and the possibility of a proximal intramural course, nine major anatomic types can be defined and account for more than 95% of the coronary variability in TGA (Fig. 49.7).

In addition, multiple ostia may be present in a given sinus, the epicardial course may be unusual, or there may be complete absence of one of the branches (e.g., absent circumflex coronary artery). If one accounted for every possible variation, the nomenclature would become too cumbersome to be useful. Therefore, this chapter uses a previously described (5) classification scheme that characterizes in text form (rather than arbitrary symbols) the nine most common variations (Fig. 49.7). Table 49.1 summarizes the frequency distribution of the coronary patterns in a number of pathologic and surgical series.

The course of the sinus node artery, which typically arises as the first branch from the right coronary artery close to its aortic origin, may be of surgical importance. Damage to the sinus node artery has been implicated in the widespread prevalence of atrial arrhythmias and sinus node dysfunction seen after atrial level (Mustard or Senning) repair (8). Although the origin and proximal course of this artery may be variable, it eventually reaches the sinus node by the interatrial groove on the anterior surface of the heart, occasionally with an intramyocardial course in the anterosuperior rim of the fossa ovalis. Because it is partially embedded in the anterosuperior portion of the atrial septum, it can be damaged easily during balloon atrial septostomy (BAS), during surgical septectomy, or when this portion of the septum is widely excised, as in the Mustard or Senning atrial switch operation.

Coexisting Anomalies

Nearly half of the hearts with TGA have no other anomaly except a persistent patent foramen ovale or a PDA. In the other half, isolated LVOTO with IVS is uncommon, about

5%. VSD is common and present in about 40% to 45% (however, one-third of the defects are small and with little hemodynamic significance), and a combination of VSD and significant LVOTO occurs in about 10%. These coexisting anomalies, together with AV valve and valve tensor abnormalities and aortic obstructive lesions, constitute additional challenges for diagnosis and surgical therapy.

Ventricular Septal Defect

The VSD is the most frequent coexisting anomaly. It may be small, large, or (rarely) multiple and can be located anywhere in the septum. The approximate distribution of VSD location includes perimembranous (conovertricular, 33%), AV septal defect (inlet septum, 5%), muscular (27%), malalignment (30%), and conal septal hypoplasia type (5%) (9).

TYPES OF VENTRICULAR SEPTAL DEFECT

The typical membranous defect lies adjacent to the membranous septum and tricuspid annulus at the anterosseptal tricuspid valve commissure and is situated between the conal (outlet) septum above and the muscular ventricular septum below. Defects in this location may close spontaneously or become smaller with time.

Most muscular defects are in the midseptum, and others occur in the posterior inflow, apical, or high anterior septum; muscular defects are rarely multiple. Spontaneous decrease in size with eventual closure has been documented frequently, particularly with an initially small, slit-shaped muscular inlet or trabecular defect.

AV septal defect (inlet septum) types of VSDs may be associated with coexisting AV valve or conduction tissue anomalies. This type of defect provides the potential for the tricuspid valve/orifice to straddle the ventricular septum and sometimes is associated with a hypoplastic right ventricle.

Of particular surgical importance are the malalignment (outlet) septal defects (Fig. 49.8). Anterior (rightward) malalignment defects are associated with varying degrees of overriding of the pulmonary annulus onto the right ventricle. With increasing degrees of overriding, a series of anomalies are encountered that culminate, effectively, in DORV with subpulmonary defect in the morphologic spectrum of the Taussig-Bing anomaly (Fig. 49.9). The VSD is an anterior defect, often with a muscular posterior rim, but it sometimes extends posteriorly to the tricuspid annulus (perimembranous extension). The subaortic stenosis caused by the anterior malalignment of the infundibular septum is frequently associated with aortic arch hypoplasia, coarctation, or even complete interruption of the aortic arch. Posterior (leftward) malalignment is associated with varying degrees of LVOTO–subpulmonary stenosis, annular hypoplasia, or even pulmonary valvar atresia (see also LVOTO). An outlet septum deficiency type of defect, also termed doubly committed subarterial defect, is characterized by an absence of the muscular outlet septum so that the defect’s superior rim is the area of fibrous continuity between the aortic and pulmonary valve annuli.

Left Ventricular Outflow Tract Obstruction

Obstruction to pulmonary blood flow is possible at multiple levels in patients with TGA. In one large clinical–surgical series (10), some form of LVOTO was present in about 25% of 260 patients, 20% of the patients with IVS (but only 5% had important hemodynamic obstructions), and 30% of the patients with VSD. Gradients measured preoperatively across the LVOT by Doppler echocardiography or during cardiac catheterization may overestimate the degree of anatomic obstruction as a result of the greatly increased pulmonary blood flow in children with TGA, especially with an associated VSD.

Figure 49.7. Coronary artery distribution in TGA. **Upper panels:** Diagnostic projection; diagram of the origin and proximal course as visualized by 2-D echocardiography and caudally angulated aortography (see text). **Lower panels:** Same coronary artery distribution as viewed anteriorly (“surgeon’s view,” frontal projection). Note that the circumflex coronary artery, or even the entire left coronary artery system, is more likely to pursue a retropulmonary course (*dashed lines*) when the great arteries are in a side-by-side relationship (*shown*). An intramural course (*shaded*) of the proximal coronary artery exists in fewer than 3% of cases but has been associated with higher risk for transfer during an arterial switch operation. Alternative terminology in *brackets* are shown as popularized by Quagebeur and Kirklin and the Congenital Heart Surgeons Society. Ant, anterior; Cx, circumflex coronary artery; Inf, inferior; LAD, left anterior descending coronary artery; Post, posterior; RCA, right coronary artery; Sup, superior. (Modified from Wernovsky G, Sanders SP. Coronary artery anatomy and transposition of the great arteries. *Coron Artery Dis* 1993;4:148–157, with permission.)

TABLE 49.1

Frequency Distribution of the Coronary Patterns in Transposition of the Great Arteries

Coronary Pattern	Cases (%)
Usual	66.9
Circumflex from RCA	16.1
Single RCA	3.9
Single LCA	1.7
Inverted	2.4
Inverted circumflex/RCA	4.2
Intramural LCA	2.1
Intramural LAD	0.1
Intramural RCA	1.0
Other	1.6

LAD, left anterior descending; LCA, left coronary artery; RCA, right coronary artery.

Modified from Wernovsky G, Sanders SP. Coronary artery anatomy and transposition of the great arteries. *Coronary Artery Dis* 1993;4:148–157; Hayes CJ, Gersony WM. Arrhythmias after the Mustard operation for transposition of the great arteries: a long-term study. *J Am Coll Cardiol* 1986;7:133–137. 143; Wetter J, Sinzobahamya N, Blaschczok HC, et al. Results of arterial switch operation for primary total correction of the Taussig-Bing anomaly. *Ann Thorac Surg* 2004;77:41–46; LacourGayet F, Serraf A, Galletti L, et al. Biventricular repair of conotruncal anomalies associated with aortic arch obstruction—103 patients. *Circulation* 1997;96:328–334.

In TGA/IVS, a dynamic type of obstruction is common, usually mild and not readily apparent on autopsy specimen without careful analysis. Angiography and echocardiography clearly demonstrate a dynamic leftward bulging of the basal muscular ventricular septum toward the lower-pressure left ventricle, which narrows the LVOT during systole (Fig. 49.4B) but opens widely during diastole. This systolic septal bulge reflects the reversal in TGA of the normal transseptal ventricular systolic pressure relationships. Dynamic obstruction is rare in the neonate with elevated pulmonary

artery resistance and left ventricular pressure or in the presence of a nonrestrictive ductus arteriosus because the left ventricle assumes systemic systolic pressure and geometry. Following atrial level repair, cardiac catheterization or Doppler echocardiography frequently demonstrates slight to moderate (10 to 40 mm Hg) systolic pressure differences across the subpulmonary outflow tract.

Fixed obstruction develops in some infants; it initially appears as a patch of endocardial thickening on the septal bulge but later can evolve into a sharp fibrous ridge or a discrete membrane, analogous to membranous subaortic stenosis, along the line of systolic mitral valve contact (Fig. 49.5). Less commonly, fixed subpulmonary obstruction is caused by a tunnel-like subpulmonary fibromuscular ridge that extends across the outflow tract and onto the base of the anterior mitral leaflet. Pulmonary valve stenosis and annular hypoplasia are rare in patients with TGA/IVS but, when present, are almost always associated with combined subvalvar obstructive lesions.

With TGA/VSD, LVOTO coexists in about 30% of patients, and the stenosis is usually more severe and complex than in TGA with IVS. The stenosis is most often subvalvar and may be a localized fibrous ring, a tunnel type of fibromuscular narrowing, or a muscular obstruction related to malposition of the outlet septum impinging into the anteromedial aspect of the subpulmonary outflow tract (Figs. 49.8A, 49.10, and 49.11). Other uncommon forms of subpulmonary stenosis result from (a) malattachment of the anterior mitral valve to the muscular outlet septum by anomalous fibrous or chordal tissue (which may be associated with varying degrees of left ventricular hypoplasia), (b) redundant tricuspid valve tissue (“pouch”) protruding through the VSD (Figs. 49.12 and 49.13), (c) subpulmonic membrane (Fig. 49.14), (d) aneurysm of the membranous septum, and (e) hypertrophy of the muscle of Moutaert.

Other Associated Anomalies

Prior to the extensive present-day use of prostaglandin E₁ therapy, a PDA was found in almost half the neonates at the initial cardiac catheterization for BAS. The ductus is usually functionally closed by 1 month of age (see sections on “Physiology and Treatment”).

Functionally important tricuspid valve anomalies were present in about 4% of surgical patients, but in autopsy series,

Figure 49.8. A: Angiocardiogram (oblique lateral view) in patient with TGA/VSD showing LVOTO due to leftward posterior malalignment of conal septum (o). Pressures were right ventricle (RV), 86/10 mm Hg; left ventricle (LV), 85/10 mm Hg; main pulmonary artery (MPA), 30/18 mm Hg. B: Right ventriculogram (frontal view) in 21-month-old with TGA/VSD showing unusually prominent obstructing subaortic outlet musculature (arrows); rightward anterior displacement (malalignment) of outlet (infundibular) septum (a); and prominent hypertrophy and anterior displacement of right ventriculoinfundibular fold (parietal band) (b). Pressures were RV, 105/6 mm Hg; AO 60/40 mm Hg; LV, 35/6 mm Hg; MPA, 26/6 mm Hg. The VSD (v) had become small and restrictive since early infancy. AO, aorta; RA, right atrium; s, interventricular septum.

Figure 49.9. Angiocardiograms (left anterior oblique views) illustrating spectrum of outflow tract morphology extending from DORV with subpulmonary VSD to TGA/VSD. **A:** DORV (Taussig-Bing type) with pulmonary trunk emerging completely or maximally from the right ventricle. Note the prominent muscular structure (o), variably termed outlet, conal, or infundibular septum, that separates the subpulmonary and subaortic outflow tract and the characteristic anterior malalignment of this outlet septum (o) relative to the rest of the ventricular septum (S). Note a second prominent subpulmonary muscle structure (x) separating the pulmonary (PV) and mitral (MV) valves. These two prominent muscle bundles are elements of the bilateral (subaortic and subpulmonary) conus present to varying degrees in these hearts. **B:** DORV with subpulmonary VSD with pulmonary trunk emerging more or less equally from both ventricles. **C:** DORV, subpulmonary VSD with pulmonary trunk emerging predominantly from left ventricle but lack of fibrous continuity between mitral and pulmonary valves. Note the prominent outlet septum (o) with malalignment relative to ventricular septum (S). **D:** TGA/VSD, outlet (o) and ventricular (S) septum are in alignment. Ao, aorta; AOV, aortic valve; LV, left ventricle; MPA, main pulmonary artery; MV, mitral valve; S, interventricular septum.

Figure 49.10. TGA/VSD and LVOTO. **A:** Left ventriculogram (left anterior oblique view) showing large VSD (v) with tunnel form of severe subpulmonary obstruction associated with some leftward posterior deviation of outlet septum (o). AV, aortic valve; LV, left ventricle; PV, pulmonary valve; RV, right ventricle; v, VSD. **B:** Two-dimensional echo (parasternal long axis view) in 2-year-old child with TGA, small VSD, and severe LVOTO. Note the subpulmonary circumferential stenosis and hypoplasia of pulmonary annulus (arrow). Aorta partially (25%) overrides the ventricular septum. At catheterization, pressures were RV, 85/12 mm Hg; LV, 85/8 mm Hg; and MPA, 37/25 mm Hg. Arterial switch was achieved with aortic translocation and biventricular outflow tract reconstruction. LA, left atrium; MPA, main pulmonary artery; MV, mitral valve; s, septum.

Figure 49.11. A: Left ventriculogram (hepatoclavicular projection). B: The companion 2-D echo (apical view) in a 4-month-old child with TGA, two muscular VSDs (*small straight arrows*) in apical and trabecular/outlet septum, and LVOTO caused by posterior-leftward malaligned outlet septum (o) and a subpulmonary fibromuscular “collar” (*large curved arrow*). At catheterization, pressures were RV 75/6 mm Hg; LV, 61/7 mm Hg; MPA, 20/12 mm Hg. AO, aorta; LV, left ventricle; MPA, main pulmonary artery; RV, right ventricle.

particularly with VSD, a considerably higher frequency (31%) was noted (11). In TGA with VSD, there may be anomalous chordal attachments to the edges of the perimembranous or outlet septum malalignment defects, and these may complicate surgical transatrial closure of the defect or construction of an intraventricular tunnel in the Rastelli operation. An unusual, infrequent, and surgically important (and remediable) type

of subpulmonary stenosis can be caused by a mass of redundant tricuspid septal valve tissue (tricuspid pouch) protruding through a VSD into the LVOT (Figs. 49.12 and 49.13). When the VSD is in the inlet septum, there may be annular overriding, tensor apparatus straddling, or both that, when extensive, may be associated with marked hypoplasia of the right ventricular sinus. Significant tricuspid valve incompetence is rare in the pre-operative heart, but it may be observed following atrial level repair (a) when severe right ventricular dysfunction can result in annular dilation and (b) in TGA with VSD when the VSD

Figure 49.12. Right ventriculogram, four-chamber view, showing outpouching of tricuspid valve tissue (*asterisk*) through a VSD into the subpulmonary area, causing significant subpulmonary obstruction. At catheterization, pressures were LV, 60/9 mm Hg; LV outflow tract, 22/9 mm Hg; and PA, 22/10 mm Hg. Ao, aorta; IVS, interventricular septum; LV, left ventricle; PA, pulmonary artery; RV, right ventricle.

Figure 49.13. Two-dimensional echocardiogram, subcostal imaging position, in 18-month-old child with TGA/VSD and outpouching (*asterisk*) of accessory tricuspid valve leaflet tissue causing significant subpulmonary obstruction. Ao, aorta; IVS, interventricular septum; LV, left ventricle; PA, pulmonary artery; RV, right ventricle.

Figure 49.14. Transvenous left ventriculogram (long-axial oblique projection) in a 7-month-old with TGA/IVS. At catheterization, there was a 45 mm Hg peak systolic ejection gradient across the LVOT resulting from a thick subpulmonary membrane (arrows). At arterial switch surgery, the membrane was found to be adherent to the anterior leaflet of the mitral valve but was adequately removed without damage to the mitral apparatus. Note the mild poststenotic dilatation of the main pulmonary artery. LV, left ventricle; MPA, main pulmonary artery. (From Wernovsky G, Jonas RA, Colan SD, et al. Results of the arterial switch operation in patients with transposition of the great arteries and abnormalities of the mitral valve or left ventricular outflow tract. *J Am Coll Cardiol* 1990;16:1446–1454, with permission.)

is repaired through the tricuspid valve. Of interest, in TGA, the ratio of tricuspid to mitral annulus circumference is <1 in almost 50% of cases, whereas in normal hearts, this ratio is always >1 .

Structural anomalies of the mitral valve have been observed at autopsy in about 20% of hearts with TGA, particularly in the VSD group; however, functionally significant lesions were present in only about 4% (9). Cleft anterior mitral valve leaflet, anomalous papillary muscles and chordae, and redundant tissue tags have been described. The most significant abnormalities from a surgical standpoint are those in which the mitral valve and portions of its tensor apparatus straddle the VSD or in which the anterior mitral valve leaflet is abnormally tethered with anomalous septal attachments and causes LVOTO.

Coarctation of the aorta, arch hypoplasia, or rarely interrupted aortic arch coexist in about 5% of patients with complete TGA, occurring much more commonly in association anterior malalignment types of VSD, especially (20%) in patients with DORV with subpulmonary defect (Taussig-Bing anomaly). The obstruction may be the usual discrete “shelf” lesion, tubular hypoplasia of the distal aortic arch, or a combination. The outlet septum may be displaced anterior and rightward vis-à-vis the trabecular interventricular septum, and there may be additional anterior encroachment by a markedly hypertrophied right ventriculofundibular fold (parietal band), both resulting in subaortic narrowing (Fig. 49.8B). The frequent association of aortic arch malformations in TGA with systemic (right) ventricular outlet obstruction is consonant with observations on malformations with normally related great arteries that link the genesis of arch anomalies with intra-

cardiac systemic (left) ventricle obstructive factors. With TGA, VSD, and arch abnormalities, there may also be hypoplasia of the tricuspid annulus and the right ventricular sinus.

Leftward juxtaposition of atrial appendages is an anomaly sometimes associated with TGA in which the right atrial appendage passes immediately behind the transposed main pulmonary artery. It occurs in about 2% to 5% of patients and can be diagnosed readily by 2-D echocardiography, angiography, or direct inspection at surgery. This anomaly is often additionally associated with major cardiac pathology, including dextrocardia, VSD, bilateral infundibulum, right ventricular hypoplasia, and tricuspid stenosis or atresia.

PHYSIOLOGY

The dominant physiologic abnormalities in TGA are a deficiency of oxygen supply to the tissues and an excessive right and left ventricular workload. The systemic and pulmonary circulations function in parallel rather than in series as in the normal infant; hence, the greatest portion of the output of each ventricle is recirculated to that ventricle (Fig. 49.15A). Particularly in TGA with IVS, only a relatively small proportion of blood is exchanged by intercirculatory shunts between the two circulations to eventually reach the appropriate vascular bed. The systemic and pulmonary arterial oxygen saturations are thus dependent on one or more of the following anatomic paths for this exchange: intracardiac (patent foramen ovale, ASD, VSD) and extracardiac (PDA, bronchopulmonary collateral circulation).

Intercirculatory Mixing

The net volume of blood passing from the pulmonary circulation (left atrium, left ventricle, pulmonary arteries) to the systemic circulation (right atrium, right ventricle, aorta) represents the anatomic left-to-right shunt and is, in fact, the effective systemic blood flow (i.e., oxygenated pulmonary venous return perfusing the systemic capillary bed) (Fig. 49.15B). Conversely, the net volume of blood passing from the systemic circulation to the pulmonary circulation represents the anatomic right-to-left shunt and is, in fact, the effective pulmonary blood flow (systemic venous return perfusing the pulmonary capillary bed). The effective pulmonary blood flow, effective systemic blood flow, and net anatomic right-to-left and net anatomic left-to-right shunts are all equal to one another, and this volume is the intercirculatory mixing: the flow in TGA on which survival depends. The net volume exchanged between systemic and pulmonary circulations must be equal over a given short interval of time because any major differences will result in a depletion of the blood volume of one circulation at the expense of overloading the other. The volumes of anatomic right-to-left and left-to-right shunted blood (i.e., “effective blood flows”) that participate in functional gas exchange at the pulmonary and systemic capillary levels are relatively small compared with the large volumes of blood circulating (total systemic and pulmonary blood flow) or recirculating (physiologic left-to-right and right-to-left shunt flows) within each circulation. The physiologic left-to-right shunt represents the volume of the pulmonary venous blood recirculating through the lungs without having passed through the body, and the physiologic right-to-left shunt is the volume of systemic venous blood reentering the systemic circulation without having passed through the lungs.

The extent of intercirculatory mixing in TGA depends on the number, size, and position of the anatomic communications and on the total blood flow through the pulmonary

Figure 49.15. The circulation in TGA. **A:** Systemic and pulmonary circulation pathways; in series, with normally related great arteries; in parallel, with TGA. *Solid arrows*, relatively unoxygenated blood; *stippled arrows*, oxygenated blood; *dashed arrows*, intercirculatory shunts. **B:** Circulation schema demonstrating flows and shunts in infants with TGA/IVS. Note that the anatomic LR shunt constitutes the effective SBF and the anatomic RL shunt, the effective PBF (see text). circuit. In the neonate with an IVS and a closed or closing ductus arteriosus, severe hypoxemia secondary to inadequate mixing at the foramen ovale level is usually present. When the interatrial or interventricular shunting sites are of adequate size, the level of arterial oxygen saturation is influenced primarily by the pulmonary-to-systemic blood flow ratio, with a high pulmonary blood flow resulting in relatively high arterial oxygen saturation. If the pulmonary blood flow is decreased by subpulmonary or pulmonary stenosis or elevated pulmonary vascular resistance, the arterial oxygen saturation will be lowered, despite adequately sized anatomic shunting sites.

The physiologic mechanisms that precisely control the equalization of interchange between the two circulations remain speculative. The shunting patterns appear to be determined by local pressure gradients, which in turn are influenced by respiratory cycle phase, compliance of the cardiac chambers, heart rate and volume of blood flow, and the vascular resistance in each of the circulations. With TGA/IVS, the interatrial shunt is from right atrium to left atrium during ventricular diastole because left ventricular resistance to filling is less than right ventricular. Pulsed Doppler echocardiography confirmed that the shunt is from left atrium to right atrium in ventricular systole because the left atrium is less distensible than the right, and the net pressure in the left atrium is higher during ventricular systole. The pattern is affected by respiration, with the interatrial right-to-left (systemic-to-pulmonary) shunt increasing during inspiration when the systemic venous return increases and pulmonary venous return decreases. Flow patterns are less well documented in the presence of a large VSD. When the defect is large and nonrestrictive, peak systolic pressures in the ventricles are equal; during ventricular systole, some right ventricular output flows preferentially to the lower-resistance pulmonary circulation, with a concomitant increase in left atrial return. During ventricular diastole, the increased pulmonary venous return favors shunting of oxygenated blood to the right atrium and ventricle. The balances between right and left atrial and ventricular compliances and pulmonary and systemic vascular resistances are important operative factors. Other important hydraulic aspects are the location of the VSD, the influence of LVOTO, and other infrequent abnormalities, such as straddling of the right AV valve across

the VSD. Infants with a large VSD but without pulmonary stenosis or increased pulmonary vascular resistance may have torrential pulmonary blood flow with high left atrial pressure, marked left ventricular volume overload, and relatively high arterial oxygen saturation, until severe heart failure with pulmonary edema intervenes.

If a large PDA persists in the neonate with TGA and IVS, bidirectional shunting at this site can be demonstrated by angiography and Doppler; however, as the pulmonary vascular resistance falls, only systemic-to-pulmonary ductal shunting persists.

Bronchopulmonary Collateral Circulation

A significant role has been postulated for the bronchopulmonary collateral circulation in TGA (10). Bronchopulmonary anastomotic channels have been visualized by angiography in more than 30% of infants with TGA under 2 years of age, and balloon occlusion studies demonstrated that these bronchopulmonary anastomotic channels functionally and freely communicate with the pulmonary vascular bed proximal to the pulmonary capillary bed (Fig. 49.16A). In addition to representing a potential intercirculatory (systemic-to-pulmonary) mixing pathway, these bronchopulmonary communications may play a role in the accelerated and more widespread pulmonary vascular disease process observed in TGA patients. Rarely, persistence of a significant bronchopulmonary collateral circulation after surgical repair results in a large enough left-to-right shunt to warrant interventional catheter embolization therapy (Fig. 49.16B) (10).

Application of the Fick principle for calculating pulmonary and systemic blood flow in infants with TGA can have major sources of error. Oxygen consumption is not normal in the severely hypoxemic infant, and assumed values are unreliable. Systemic and pulmonary arteriovenous oxygen differences may be quite small; consequently, minor errors in oxygen saturation measurement introduce large errors in calculations of flow. Furthermore, the contribution to pulmonary blood flow from the bronchopulmonary collateral circulation enters the pulmonary vascular circuit distal to the usual catheter sampling sites. The true mixed pulmonary artery saturation

Figure 49.16. A: Preoperative transvenous descending aortogram in a neonate with TGA/IVS showing enlarged bronchial arteries (following the right main stem bronchus) to the right lung. B: Same patient 42 years after a primary arterial switch; a selective injection in the same bronchial artery shows a markedly enlarged vessel, with prompt visualization of the pulmonary veins and left atrium on levophase. At the postoperative catheterization, the left ventricular end-diastolic pressure was elevated at 18 mm Hg, and M-mode echocardiographic measurements of left ventricular end-diastolic dimension were increased, suggesting a significant volume overload. Following successful coil embolization, the left ventricular end-diastolic pressure fell to 7 mm Hg, and the echocardiographic indices normalized.

present at the precapillary level cannot be sampled; therefore, a falsely high pulmonary artery oxygen saturation and blood flow calculation will result. A modest bronchopulmonary contribution (20%) to the pulmonary precapillary blood flow can result in 30% overestimation of pulmonary blood flow; hence, calculated pulmonary vascular resistance always should be viewed as minimum values. Pulmonary blood flow in TGA is less when derived from angiographic stroke volume measurements compared with Fick measurements. With IVS, the pulmonary blood flow by angiography was within the range for normal infants in the first few weeks of life but averages approximately twice the normal flow in older infants and children, presumably because of the progressive changes in pulmonary vascular resistance and ventricular compliance that occur with age.

Determinants of the magnitude of pulmonary blood flow in TGA remain obscure. A major fall in pulmonary artery pressure and vascular resistance occurs during the first few days and weeks of life in TGA/IVS, and therefore, the early maturation of the pulmonary circulation has been considered similar to that of the normal infant. Left ventricular compliance progressively increases during this time, in association with decreasing left ventricular muscle mass. The outputs of the two ventricles are determined presumably by their respective preload, compliance, afterload, and contractility but must be autoregulated constantly by some remarkable mechanism to meet the special requirements of the unique transposition intercirculatory shunt; that is, that the net flow from the pulmonary to the systemic circuit equals the net flow from the systemic to the pulmonary circuit.

In the neonate with TGA/IVS who has been palliated by balloon septostomy or surgical atrial septectomy, the pulmonary blood flow pattern should resemble that in an

infant with normally related great arteries and isolated large secundum ASD; that is, as the pulmonary vascular resistance falls, the pulmonary ventricle circulates an increased blood volume at low pressure. In TGA, this increased level of pulmonary blood flow will result in improved intercirculatory mixing and systemic arterial oxygen saturation, assuming that an adequately sized and favorably placed anatomic opening was created (see also section on Fetal and Perinatal Physiology).

If the pulmonary blood flow decreases in a patient with TGA as a consequence of increasing LVOT stenosis or pulmonary vascular resistance, the intercirculatory mixing and systemic arterial oxygen saturation also will decrease. It is important to stress, however, that not all infants with progressive cyanosis with the combination of TGA and LVOTO are progressively more hypoxemic as a result of decreasing pulmonary blood flow. Progressive restriction of a catheterization or surgically created atrial communication can limit intercirculatory mixing and may cause progressive cyanosis. Cardiac catheterization is mandatory to assess the adequacy of pulmonary blood flow and the interatrial communication in these infants, especially if a palliative aortic-pulmonary shunt is being considered (see also section on Surgery).

There is a prevalent but clinically silent maldistribution pattern of pulmonary blood flow in TGA patients (12). Pulmonary angiograms, radionuclide lung perfusion images, and chest roentgenograms indicate that about half the patients with complete TGA have a significantly greater proportion of blood flow distributed to the right lung than normal (Fig. 49.17). The maldistribution is dependent on a common anatomic feature found in transposition, that is, abnormal rightward inclination of the main pulmonary artery, which results in a straight ejection direction from left ventricle to

Figure 49.17. Abnormal distribution of pulmonary blood flow favoring the right lung in TGA observed prior to surgery. Pulmonary and radionuclide angiograms from four patients. **A:** Normal right–left distribution. **B:** Slight rightward distribution. **C:** Moderate rightward distribution. **D:** Marked preferential rightward distribution.

main pulmonary artery to right pulmonary artery. Under these morphologic circumstances, the momentum of blood flow in the main pulmonary artery carries the blood preferentially into the right pulmonary artery. The abnormally increased distribution of pulmonary blood flow to the right lung in TGA often is associated with some degree of hypoplasia of the left pulmonary arterial vessels and is further manifested in the occasional reports of unilateral, always left-sided, pulmonary vein stenosis or hypoplasia at catheterization or atrial switch surgery (13–15). It is unlikely that this phenomenon of pulmonary blood flow maldistribution has any significant effect on the clinical course of TGA. Further, these maldistribution patterns are not observed in patients who have neonatal arterial switch repair.

In the neonate with IVS, the systemic arterial PO_2 may be as low as 15 to 25 mm Hg at presentation, with resultant anaerobic glycolysis and severe metabolic acidemia. The newborn infant may not manifest acidemia in the first day or two of life, perhaps because of favorable blood tissue dissociation characteristics or tissue resistance factors. Inevitably, unless intracardiac mixing is improved by palliative or corrective intervention, severe hypoxemia results in advanced acidemia, hypoglycemia, hypothermia, and eventual death.

Arterial Blood Gases and Metabolic Responses

In TGA with poor intercirculatory mixing, the contrast between systemic arterial and pulmonary venous blood gases while the patient is breathing room air is striking. The pulmonary venous blood reflects chemoreceptor-stimulated hyperventilation; in room air, the PO_2 levels may be increased to as high as 110 mm Hg and the PCO_2 levels reduced to 15 to 25 mm Hg. In contrast, systemic arterial PO_2 levels are rarely higher than 35 mm Hg, and the PCO_2 is usually normal or only slightly elevated (<45 mm Hg) because of the limited anatomic left-to-right (effective systemic blood flow) shunt. Arterial blood gases obtained in both room air and 100% oxygen are helpful in discriminating cyanotic infants with TGA from those with lung disease. The response of systemic arterial PO_2 to 100% oxygen administration is related primarily to the extent of intercirculatory mixing rather than to the increase in pulmonary venous oxygen content derived

from dissolved oxygen. When systemic arterial PO_2 values are <30 mm Hg in room air and remain below 35 to 40 mm Hg during high-oxygen-content breathing, poor intracardiac mixing is present.

Fetal and Perinatal Physiology

Fetal Circulation

Both TGA physiology and anatomy appear compatible with normal fetal survival and relatively normal gestational development. The course of fetal circulation is modified because the right side of the heart ejects blood directly into the ascending aorta, in contrast to the sequence in the normal fetus, where the right ventricle ejects essentially into the descending aorta via the PDA. In the fetus with TGA, the superior vena caval blood is directed through the tricuspid valve to the right ventricle and ascending aorta and provides blood of slightly lower glucose concentration and PO_2 to the coronary and cerebral circulations than in the normal fetus. The blood entering both the pulmonary circulation and the descending aorta is derived mainly from the glucose- and oxygen-rich placental return that has shunted across the patent foramen ovale and may be expected to have a glucose concentration and PO_2 somewhat higher than that found in normal fetuses.

The clinical effects of these abnormalities of fetal flow remain to be precisely defined. In one pathology study, infants with TGA had cardiac and central nervous system structures similar in size and weight to control values; however, increased numbers (270% of control) and size (220% of control) of pancreatic islet cells, as well as a significantly increased weight of the adrenal cortex (116% of control), were found in infants with TGA (16). These findings in the pancreas and adrenal cortex are similar to those seen in infants of diabetic mothers and support the contention that the higher-than-usual glucose concentration in the descending aorta during fetal development may play a role.

It is increasingly recognized that the transposed fetal circulation results in lower substrate delivery to the rapidly developing brain, particularly in the second half of pregnancy (17–19). This may account for, in part, the higher-than-expected incidence of microcephaly, white matter injury, and immaturity of the brain seen on MRI scans of neonates with TGA (20–22).

Transitional Circulation

After birth, the pulmonary vascular resistance falls with expansion of the lungs and pulmonary blood flow and left atrial pressures increase in accordance with the more or less normal neonatal transitional physiology. The systemic vascular resistance increases because of removal of the low-resistance placental circulation. In the normal neonate, the right atrial pressure falls as the right side of the heart faces the rapidly decreasing pulmonary vascular resistance and the interatrial pressure difference favors closure of the septum primum flap over the foramen ovale. With TGA, however, the right atrial pressures are increased, and the similarity of atrial pressures tends to keep the foramen ovale open (incompetent valve), with resulting bidirectional shunting (see section on Intercirculatory Shunting).

In TGA with IVS, the ductus arteriosus is often widely patent after birth. Early after birth, when pulmonary vascular resistance is still high, there is bidirectional ductal flow: in systole, left ventricle–pulmonary artery–ductus–descending aorta; and in diastole, aorta–ductus–pulmonary artery. With continued fall in pulmonary vascular resistance, the shunt at the PDA is primarily from aorta to pulmonary artery (effective pulmonary blood flow), with an equal amount of blood passing from the pulmonary circuit to systemic circuit at the atrial level (effective systemic blood flow). Rarely, there is a delayed fall in pulmonary vascular resistance that results in persistent pulmonary hypertension, little ductal shunting, and limited intercirculatory mixing. Urgent balloon septostomy or even surgical septectomy may not improve the severe hypoxemia, and these neonates may need urgent support with early repair, extracorporeal membrane oxygenation, or both. Finally, severe hypoxemia in some neonates may be due to an intact or virtually intact atrial septum. Despite a widely PDA, there is poor intercirculatory mixing at this site alone; the primarily aorta–pulmonary artery shunting cannot be “balanced” by an equal volume of shunting from left atrium to right atrium. These neonates are typically severely hypoxemic and acidotic shortly after birth, may have severe pulmonary edema and hemorrhage, and may not survive if septostomy or arterial switch repair cannot be accomplished in a timely fashion. The *only* way to provide oxygenated blood to the coronary arteries and brain is via a shunt from left atrium to right atrium (and then to the right ventricle and aorta). Thus, the neonate with an intact (or virtually intact) atrial septum cannot survive with an open ductus arteriosus alone; an emergency BAS is necessary (see section on “Treatment”).

During the brief perinatal transitional interval, there may be enough intercirculatory mixing to limit cyanosis and avoid severe hypoxemia; however, in most such infants, the ductus soon constricts with resulting increased hypoxemia. At this time, when oxygen delivery to the tissues is seriously compromised, the newborn's oxygen consumption is rapidly increasing because of increased body metabolism, the need to maintain body temperature, and β -adrenergic receptor stimulation. These factors further decrease mixed venous—and hence arterial—oxygen saturation because most of the circulating systemic blood flow is the recirculated systemic venous return. An additional negative factor during this critical neonatal period is the presence of a high proportion of fetal hemoglobin, which limits oxygen extraction by the tissues because of its high affinity for oxygen. Finally, there are serious metabolic consequences to severe arterial hypoxemia, including increased anaerobic metabolism, excessive lactate production, depletion of glycogen stores, and metabolic acidosis with the eventual catastrophic outcome of generalized impaired cellular function. The importance of the ductus arteriosus in maintaining and increasing intercirculatory

mixing in the early postnatal period explains the value of infusion of prostaglandin E_1 , particularly in infants with TGA/IVS, but only when there is also an atrial communication to allow pulmonary venous return to reach the ascending aorta.

Pulmonary Vascular Disease

The early development and widespread presence of pulmonary vascular obstruction in patients with TGA have been widely documented by autopsy findings, biopsy studies, and hemodynamic data (23–27). Compared with most other forms of congenital heart disease with increased pulmonary blood flow, TGA has an apparent accelerated rate of development and an increased frequency of this complication. Histologic evidence for advanced pulmonary vascular disease grade 3 or greater using Heath–Edwards (H–E) classification is almost the rule in infants over 1 year of age with large VSD and pulmonary artery pressures at or near systemic level. In one study by Newfeld et al. (23), 25 of 28 children older than 1 year with persistent large VSD had grade 4 H–E histologic changes present (Fig. 49.18). Significant subpulmonary or pulmonary stenosis (i.e., peak systolic pulmonary artery pressure <50% of peak systolic left ventricular pressure) usually prevents the early occurrence of advanced pulmonary vascular disease in patients with large VSD and increased pulmonary blood flow. Even in infants and children with TGA/IVS, extensive abnormal histologic changes have been noted, although the process seems somewhat slower and much less prevalent than with large VSD. Microthrombi, in addition to the classical vascular pathology, were identified in the pulmonary vessels of 23% of the lung specimens, and these may represent an etiologic factor. The persistence of a large PDA in infants with IVS has been implicated as a cause for increased pulmonary vascular disease as has prolonged hypoxemia or polycythemia.

A summary of four comprehensive histologic studies (27) indicated that patients with TGA and large VSD have pulmonary vascular changes grade 3 or greater occurring in 20% before 2 months of age, 25% from 3 to 12 months, and 78% after 12 months of age. The comparable findings for TGA patients with IVS were 1% before 2 months, 17% from 3 to 12 months, and 34% after 12 months of age.

Rarely, the occurrence, or more likely progression, of pulmonary vascular obstruction has been noted even after successful atrial correction in infants with preoperative documentation of minimal pulmonary hypertension preoperatively (23–28). The pathogenesis of the more accelerated and widespread pulmonary vascular disease in TGA is undoubtedly multifactorial. Although the pulmonary vascular bed may be functionally normal at birth, histologic studies indicate that shortly thereafter an accelerated pathologic process occurs. Pulmonary vascular morphometry in a number of congenital cardiac malformations has shown that, in addition to the marked increases in pulmonary vascular muscularity and intimal hyperplasia with vessel obstruction, there is a reduction in the number of intra-acinar pulmonary arteries in patients with elevated pulmonary vascular resistance. Intense systemic hypoxemia is commonly present, and local pulmonary hypoxemia can result from increased bronchial arterial vessels and bronchopulmonary anastomoses carrying hypoxemic systemic blood to the precapillary pulmonary arterioles. Thus, increased pulmonary vascular flow, pressure, and vasoconstrictive factors, possibly in association with abnormal platelet and red cell factors, can result in increased pulmonary vessel shear stress, endothelial damage, microthrombi, and the early induction and rapid progression of vascular disease. These findings suggest that the pulmonary vascular state

Figure 49.18. Pulmonary vascular disease in patients with TGA. Age, plotted with log 2 scale progression in days and years; *vertical arrow* indicates 1 year of age; *horizontal arrow* indicates separation between grades 1 to 2 pathology and grades 3 to 4 pathology. Grade 3, occlusive intimal fibrosis and grade 4, plexiform lesions and vascular dilatation, represent advanced pulmonary vascular disease. N, normal vascular histology; PDA, patent ductus arteriosus; PAB, pulmonary artery banding; PS, pulmonary stenosis. (From Newfeld EA, Paul MH, Muster AJ, et al. Pulmonary vascular disease in complete transposition of the great arteries: a study of 200 patients. *Am J Cardiol* 1974;34:75–82; Newfeld EA, Paul MH, Muster AJ, et al. Pulmonary vascular disease in transposition of the great vessels and intact ventricular septum. *Circulation* 1979;59:525–530, with permission.)

may influence the rate of destruction of platelets and platelet aggregate formation in the lung and perhaps contribute to the rapid progression of pulmonary vascular disease. The implications of these findings are clear in regard to the timing of surgery to minimize initiation or progression in pulmonary vascular obstructive disease processes. In the current era of wide success with arterial switch repair within the first few weeks of life, progressive pulmonary vascular obstructive disease will likely become infrequent, just as has occurred with early repair in patients with large VSD and normally related great arteries.

The quantitative assessment of pulmonary vascular resistance at catheterization in TGA can be beset with problems. It may not be possible to enter the pulmonary artery for pressure measurements. Application of the Fick principle tends to overestimate pulmonary blood flow and hence underestimate pulmonary vascular resistance (see also section on “Intercirculatory Mixing”). A limited comparison of Fick-estimated pulmonary vascular resistance with histologic grading suggested that patients with advanced

pathology (grade 4, H–E) usually have pulmonary vascular resistance >7 to 8 U and mean pulmonary artery pressures >55 mm Hg (23).

CLINICAL MANIFESTATIONS

In the past, the conventional diagnostic sequence for an infant with suspected TGA was physical examination, electrocardiogram (ECG), and chest roentgenogram, followed by cardiac catheterization, angiography, and usually concurrent palliative BAS. Presently, 2-D and Doppler echocardiography can provide sufficiently detailed information for the cardiac surgical team to proceed directly with an arterial switch operation in the appropriate neonate. If necessary, BAS can be performed and assessed under 2-D echocardiographic visualization. Nevertheless, an understanding and integration of the following clinical components of diagnosis are useful for the comprehensive management of infants with this malformation.

TABLE 49.2

Transposition of the Great Arteries: Physiologic–Clinical Classification

I	TGA (IVS or small VSD) with increased PBF and small ICS ^a
II	TGA (VSD large) with increased PBF and large ICS
III	TGA (VSD and LVOTO), with restricted PBF
IV	TGA (VSD and PVOD), with restricted PBF

^aA subgroup with large PDA has similar characteristics to group II.

IVS, intact ventricular septum; VSD, ventricular septal defect; PBF, pulmonary blood flow; ICS, intercirculatory shunting; PVOD, pulmonary vascular obstructive disease; LVOTO, left ventricular outflow tract obstruction.

Cyanosis, hypoxemic deterioration, or heart failure with early death summarizes the usual clinical course in the untreated infant with complete TGA. The clinical manifestations and course are influenced predominantly by the extent of intercirculatory mixing, which, in turn, depends on several anatomic and functional factors that can be integrated into a useful clinical classification (Table 49.2).

Transposition of the Great Arteries (IVS or Small VSD) with Increased Pulmonary Blood Flow and Small Intercirculatory Shunt

Prominent hypoxemia (“cyanosis”) is an early and almost universal finding in the neonate with TGA who has inadequate intercirculatory mixing (group I). The cyanosis may be initially mild (see section on “Fetal and Perinatal Physiology”) but is rapidly progressive. In neonates diagnosed after birth, cyanosis was recognized by the nursery staff or physician within the first hour of life in 56% and during the first day of life in 92% of neonates with TGA and IVS (29). Early diagnosis and prompt therapy for the neonate with TGA/IVS are critical. Undue emphasis has been placed in the past on diagnostic features, such as significant systolic murmur, heart failure, cardiomegaly, and cardiopulmonary distress. For this subgroup, it must be recognized that beyond cyanosis, the clinical examination is often unrewarding with regard to useful diagnostic physical findings. Even the chest roentgenogram and ECG may be normal in appearance in the immediate newborn period. In the current era, prompt echocardiographic examination is clearly indicated for any cyanotic neonate with suspected congenital heart malformation.

Reverse differential cyanosis, that is, cyanosis of the upper body greater than that of the lower body, is rare and always indicates the presence of TGA with a PDA and pulmonary artery to aortic shunting. In the neonate with TGA and an IVS and uncomplicated large PDA, this pattern may be transiently observed, particularly if pulmonary vascular resistance remains high. Importantly, reverse differential cyanosis suggests a more complex TGA malformation including an aortic arch anomaly, such as coarctation of the aorta or interruption of the aortic arch, or TGA with suprasystemic pulmonary vascular resistance.

On physical examination, the neonate, if seen early, will appear healthy and well developed except for cyanosis. With time, one of two clinical pictures emerges: either hypoxemia (TGA with intact or virtually IVS) or heart failure (TGA with large VSD). Early systolic ejection sounds are rare; the first heart sound is normal or loud. No systolic murmur is heard in most neonates, and those heard are typically soft, grade 2/6 or less. These systolic murmurs are ejection in quality, maximum at the middle and upper left sternal border, and probably represent a functional LVOT murmur related to increased blood flow velocity or a closing PDA.

A large, persistent PDA can modify the clinical findings in the neonate with TGA/IVS because a large intercirculatory shunt may be present. Characteristically, these infants present quite early with prominent tachypnea and relatively slight cyanosis. Importantly, the classic signs indicative of a large PDA, such as continuous murmur, bounding pulses, and a prominent middiastolic rumble, are present in fewer than half of this group. The risk for necrotizing enterocolitis may be increased in neonates with TGA and a large PDA. In these infants, the mesenteric circulation may be at risk because of (a) retrograde diastolic flow in the descending aorta producing a “steal” phenomenon, (b) decreased oxygen delivery, and (c) cardiac catheterization/angiography and umbilical artery catheterization in some cases.

Transposition of the Great Arteries (Large VSD) with Increased Pulmonary Blood Flow and Large Intercirculatory Shunt

The neonate with a large VSD may not manifest any signs or symptoms of heart disease initially, although mild cyanosis, most evident during crying, may be noted in the nursery. Characteristically signs of congestive heart failure develop within 2 to 6 weeks. Tachypnea and tachycardia become prominent; cyanosis, although evident with stress and crying, may remain quite mild and be overlooked. Heart murmurs also may be minimal initially, but a prominent grade 3 to 4/6 pansystolic murmur, third heart sound with middiastolic rumble, gallop rhythm, and narrowly split second heart sound with loud pulmonary component eventually emerge in these infants.

Transposition of the Great Arteries (VSD and LVOTO) with Restricted Pulmonary Blood Flow

Neonates with TGA, VSD, and severe pulmonary stenosis or atresia have diminished pulmonary blood flow. They represent a relatively small proportion (5% to 8%) of the neonatal TGA population. Clinical findings are similar to those in the infant with tetralogy of Fallot with severe pulmonary stenosis or atresia, and the cyanosis is extreme from birth.

Transposition of the Great Arteries (VSD and Pulmonary Vascular Obstructive Disease) with Restricted Pulmonary Blood Flow

Pulmonary vascular obstructive disease is not present in the newborn with TGA. Progressively advancing pulmonary vascular disease may not be evident early from physical findings. A secondary increase in cyanosis with increasing hematocrit in infants who have had successful palliative procedures always should raise the suspicion of a decrease in pulmonary blood flow caused by progression either in pulmonary vascular disease or in LVOT stenosis. With advanced pulmonary vascular obstructive disease, an early systolic ejection sound is commonly heard. There may be no murmurs present or only a faint short ejection systolic murmur. Eventually, in later childhood or adolescence, a high-pitched, blowing early decrescendo diastolic murmur of pulmonary insufficiency and a blowing apical murmur of mitral insufficiency result from gross dilation of the left heart.

Central Nervous System

Associated anatomic abnormalities of the central nervous system are rare in children with TGA, although head circumference is slightly less than normal (20). Spontaneous

cerebrovascular accidents, particularly in infants younger than 2 years of age, were an infrequent but tragic complication in the past for the inadequately palliated or uncorrected infant. The recent decrease in frequency undoubtedly is related to programs achieving more satisfactory early palliation or correction. The most common presentation is the sudden onset of hemiparesis. Hypochromic, microcytic anemia in conjunction with severe hypoxemia has been implicated as a mechanism for cerebrovascular accidents in the neonate and young infant. In the older child, polycythemia and the increased blood viscosity secondary to long-standing, severe hypoxemia have been regarded as the etiologic factors.

Brain abscesses have been infrequent: when they occur, they are almost always in a surgically uncorrected patient over 2 years of age, in contrast to cerebrovascular accidents, which occur most commonly in infants younger than 2 years of age. Symptoms such as persistent headache or, less frequently, slowly developing neurologic abnormalities distinguish this complication from acute cerebrovascular accident.
